medium- and low-pressure decomposers (i, j), operating at 19 and 3 bar, respectively. Ammonia and carbon dioxide separated from the urea solution here are recovered through stepwise absorption in the low- and medium-pressure absorbers (h, k). Condensation heat in the medium-pressure absorber is transferred directly to the aqueous urea solution feed in the final concentration section. In this final concentration section (l), the purified urea solution is concentrated further either by a two-stage evaporation up to 99.7 % for urea prill production or by a single evaporation up to 98.5 % for urea granule production. Water vapor formed in the final concentrating section is condensed in surface condensers (q) to form process condensate. Part of this condensate is used as an absorbent in the recovery sections, whereas the remainder is purified in the process condensate treatment section by hydrolysis and steam stripping, before being discharged from the urea plant.

The highly concentrated urea solution is finally processed either through the prilling tower (o) or via the urea granulator (p). Instead of concentration via evaporation, the ACES process can also be combined with a crystallization section to produce urea with low biuret content.

Until now, the ACES process has been used in seven urea plants.

3.3.2.4. Isobaric Double-Recycle Process
[26], [28], [50]

The isobaric double-recycle (IDR) stripping process, developed by Montedison, is characterized by recycle of most of the unreacted ammonia and ammonium carbamate in two decomposers in series, both operating at the synthesis pressure. A high molar $NH_3 : CO_2$ ratio (4 : 1 to 5 : 1) in the reactor is applied. As a result of this choice of ratio, the reactor effluent contains a relatively high amount of nonconverted ammonia. In the first, steam-heated, high-pressure decomposer, this large quantity of free ammonia is mainly removed from the urea solution. Most of the residual ammonia, as well as some ammonium carbamate, is removed in the second high-pressure decomposer where steam heating and CO_2 stripping are applied. The high-pressure synthesis section is followed by two lower-pressure decomposition stages of traditional design, where heat exchange between the condensing off-gas of the medium-pressure decomposition stage and the aqueous urea solution to the final concentration section improves the overall energy consumption of the process. Probably because of the complexity of this process, it has not achieved great popularity so far. The IDR process or parts of the process are used in four revamps of older conventional plants.

3.3.3. Other Processes

Urea – Ammonium Nitrate (UAN) Production. Mixtures of urea (*mp* 133 °C) and ammonium nitrate (*mp* 169 °C) with water have a eutectic point at −26.5 °C [51]. As a result solutions with high nitrogen content can be made with solidification temperatures below ambient temperature. These mixtures, called UAN solutions, are used as liquid nitrogen fertilizers.

UAN solutions can be made by mixing the appropriate amounts of solid urea and solid ammonium nitrate with water or, alternatively, in a production facility specially designed to produce UAN solutions. In this latter category the Stamicarbon CO_2-stripping technology is especially suitable. In a partial-recycle version of this process, unconverted ammonia emanating from the stripped urea solution and from the reactor off-gas is neutralized with nitric acid. The ammonium nitrate solution thus formed and the urea solution from the synthesis section are mixed to yield a product solution with the desired nitrogen content (32 – 35 wt %) directly. Such a plant designated for the production of UAN solutions is cheaper than the separate production of urea and ammonium nitrate in investment and in operating costs, because evaporation, final product shaping for both urea and ammonium nitrate, and wastewater treatment sections are not required.

Integrated Ammonia – Urea Production. Both feedstocks required for urea production, ammonia and carbon dioxide, are usually obtained from an ammonia plant. Since an ammonia plant is a net heat (steam) producer and a urea plant is a net heat (steam) consumer, it is normal practice to integrate the steam systems of both plants. Since both processes usually contain a process condensate treatment section where

volatile components are removed by steam stripping, the advantages of combining these sections have been explored [52–54]. Several attempts for further integration of mass streams of both processes have been published [55–59]. Despite the claimed reduction in both capital and raw material cost, these highly integrated process schemes have not gained acceptance mainly because of their increased complexity.

3.4. Effluents and Effluent Reduction

Gaseous Effluents. There are potentially two sources for air pollution from a urea plant: (1) gaseous ammonia emission from continuous process vents, and (2) urea dust and ammonia emissions from the finishing section (prilling or granulation).

Gaseous Emissions from Process Vents. Noncondensable gases enter the urea process as contaminants in the raw materials, as process air introduced for corrosion protection, and as air leaking into the vacuum sections of the process. At places where these noncondensable gases are vented, proper measures should be taken to minimize ammonia losses. The present state of the art allows reduction of these losses to <0.2 kg of ammonia per tonne of urea produced. This is realized by using conventional absorption techniques. Special attention is required to avoid explosive gas mixtures originating from combustibles (hydrogen, methane) present in the carbon dioxide and ammonia feedstocks, and the air introduced for anticorrosion purposes. Catalytic combustion of the hydrogen present in carbon dioxide, and dosing of nitrogen or excessive amounts of combustibles have been suggested to avoid the risks of formation of explosive gas mixtures [60].

Gaseous Emissions from the Finishing Section (Prilling/Granulation). In the prilling processes, urea dust is produced, mainly from evaporation and subsequent sublimation of urea, but also partly via a chemical mechanism: formation of ammonia and isocyanic acid in the urea melt, evaporation of these components, followed by sublimation of this ammonia – isocyanic acid mixture to form urea dust in the colder air. Urea dust formed in this way is typically very fine (0.5 – 2 μm). Removal of this fine urea dust from the prilling tower exhaust gas is a technical challenge. Because of the small particle size, dry cyclones cannot be used. Instead, wet impingement type devices have proved successful in removing a major part of the dust from the air.

Many new urea plants use granulation instead of prilling as the finishing technique. The main purpose is to improve the size and strength of the product, but less difficulty in controlling dust emissions is also an advantage. The dust produced in these granulation devices (fluidized-bed granulation or drum granulation) is typically much coarser than the fume-like dust produced in a prilling tower.

This results basically from the much shorter contact time of liquid urea with air. Because of the coarser dust and the smaller air quantities to be handled, wet scrubbers provide adequate and much simpler dust emission control for granulation units compared to the apparatus required for emission control in prilling.

Liquid Effluents. The process condensate produced from the evaporation or crystallization sections of the plant contains 3 – 8 wt % ammonia and 0.2 – 2 wt % urea. Two techniques are known to remove these pollutants:

1) Biological treatment [61–63]
2) Chemical hydrolysis and steam stripping to remove ammonia from the condensate

Biological treatment seems to have gained only slight acceptance. The method involving chemical hydrolysis and steam stripping recycles urea (in the form of ammonia) and ammonia to the synthesis section for the production of urea, whereas with biological treatment the urea and ammonia present in the feed to wastewater treatment are lost to urea production. Several chemical hydrolysis and steam-stripping systems are described below.

Stamicarbon System. In the Stamicarbon system [64] first the bulk of ammonia is removed by pre-desorption of the process condensate, followed by hydrolysis of the urea with steam at 170 – 230 °C to form ammonia and carbon dioxide via ammonium carbamate. The hydrolyzer is a vertical bubble-washer column, operated in countercurrent with respect to gas and liquid flow. Ammonia remaining in the process condensate is then removed by further steam stripping (desorption). Since both

the pre-desorber and the desorber operate at low pressure (1 – 5 bar), low-pressure steam as produced in the urea synthesis section can be used as stripping agent. The combination of pre-desorption and countercurrent operation of the hydrolyzer ensures that the chemical equilibrium of the hydrolysis reaction does not limit the minimum achievable urea content in wastewater to concentrations <1 ppm. Also, the remaining NH_3 concentration is <1 ppm.

Snamprogetti System. The Snamprogetti system [65] also includes a system of pre-desorption, hydrolysis, and final desorption with steam stripping. In this process, however, the hydrolyzer is built as a horizontal column with cross-flow operation with respect to gas and liquid flow. Hydrolysis is carried out at somewhat higher temperature (230 – 236 °C) and pressure (33 – 37 bar) than in the Stamicarbon process. Also, this process claims minimum achievable NH_3 and urea concentrations <1 ppm in the liquid effluent.

Toyo Engineering Corporation also offers a system of pre-desorption and hydrolysis, followed by final desorption, as part of its ACES and conventional urea processes. Urea and ammonia concentrations <5 ppm in the effluent are claimed.

UTI System. In the UTI system [66], desorption and hydrolysis take place in a single column, in which the hydrolysis of urea back to ammonium carbamate is carried out concurrently with the stripping of ammonia from the liquid phase. Because of this concept, both the steam required for steam stripping and the steam required to bring the process condensate to a sufficiently high temperature for hydrolysis must be at medium pressure. A small amount of carbon dioxide is fed to the bottom of the column. The system is claimed to achieve residual NH_3 concentrations <10 ppm.

Other Systems. Some systems have been proposed [52–54] in which the wastewater treatment sections of the urea and ammonia plants are combined. Like the systems described above, they also remove urea by hydrolysis to ammonia and carbon dioxide, which are subsequently removed by transferring them into a steam-containing gas phase. The principal difference between these systems and the aforementioned methods is that the ammonia and carbon dioxide produced are recycled to the ammonia plant reforming system, rather than to the urea synthesis section.

3.5. Product-Shaping Technology

Prilling. For a long time, prilling has been used widely as the final shaping technology for urea. In prilling processes, the urea melt is distributed in the form of droplets in a prilling tower. This distribution is performed either by showerheads or by using a rotating prilling bucket equipped with holes. Urea droplets solidify as they fall down the tower, being cooled countercurrently with up-flowing air. The prilling process has several drawbacks:

1) The size of the product is limited to a maximum average diameter of about 2.1 mm. Larger-size product would require uneconomically high prilling towers; moreover, larger droplets tend to be unstable.
2) Very fine dust is formed in the prilling process (see Section 3.4). Removal of this dust is a technically difficult and expensive operation.
3) The crushing strength and shock resistance of prills are limited, making prilled product less suitable for bulk transport over long distances. This problem can be largely overcome with appropriate techniques to improve the physical properties, such as seeding [67] to improve shock resistance or addition of formaldehyde to improve crushing strength, and to suppress the caking tendency.

Granulation [29], [68–70]. The drawbacks of prilling have initiated the development of several granulation techniques. These techniques deviate from the prilling technique in that the urea melt is sprayed on granules, which gradually increase in size as the process continues. The heat of solidification is removed by cooling air or, for some granulation techniques, evaporation of water. Since the contact time between liquid urea and air in these processes is much lower than in prilling, the dust formed in granulation processes is much coarser; therefore, it can be removed much more easily from the cooling air.

Drum granulation systems have been developed, for example, by C & I Girdler,

Kaltenbach – Thuring, and Montedison. *Pan granulation processes* have also been developed, for example, by Norsk Hydro and the Tennessee Valley Authority (TVA). More recently *spouted-bed* and *fluidized-bed granulation techniques* were introduced. A spouted-bed technique was developed by Toyo Engineering Corporation; however, the fluidized-bed technology from Hydro Agri seems to be most successful at this time.

All granulation processes require the addition of formaldehyde or formaldehyde-containing components. Also common to all granulation techniques is that they yield products with larger diameters compared to prilling. However, their capabilities in this respect differ from each other to quite an extent.

Although the improvements brought about by granulation are beyond doubt, prilling techniques still have a place because of the lower investment and lower variable costs associated with prilling compared to granulation.

4. Forms Supplied, Storage, and Transportation

Forms Supplied. Urea may be supplied either in solid form or as a liquid. For *liquid compound fertilizers*, urea is a favorite ingredient. It is generally used in combination with ammonium nitrate as an aqueous solution to obtain liquids containing 32 – 35 wt % nitrogen. These solutions are designated as UAN-32 to UAN-35.

The *solid forms* are generally classified as granular or prilled products, because of the differences in handling properties. Prilled product is considered less suitable for bulk transportation because prills have lower crushing strength, a lower shock resistance, and a higher caking tendency than granules. Because of this, prilled products are usually marginally cheaper than granulated product. Granulated product usually also has a larger diameter (2.0 – 2.5 mm) than prills (1.5 – 2.0 mm), making granules more suitable for bulk blending to produce compound fertilizers.

Special Grades. The majority of urea is designated as "fertilizer grade"; however, some special forms have found limited application:

Technical Grade. Technical-grade urea should be without additions; color, ash-, and metal content are sometimes also specified. For urea used to produce urea – formaldehyde resins, its content of pH-controlling trace components is important. Because of this, technical-grade urea at present is mostly traded as a performance product, rather than being bound to narrow specification limits. The fitness of the product for use is judged by application-specific tests.

Low-Biuret Grade. A maximum biuret content up to 1.2 wt % is considered acceptable for nearly all fertilizer applications of urea. Only for the relative small market segment of foliar spray to citrus crops is a lower biuret content (max. 0.3 %) desirable.

Feed Grade. Some urea is also used directly as a feed component for cattle. Urea used for this purpose should be free of additions. Feed-grade urea is supplied in the form of microprills with a mean diameter of about 0.5 mm.

Slow-Release Grades. Studies show that only 50 – 60 % of fertilizer nitrogen applied to soil is usually recovered by crop plants. Several attempts have been made to increase this percentage by slowing the release of fertilizer to the ground via coating or additions [71].

Urea Supergranules. Granulated product with a very large diameter (up to 15 mm) has found limited application for deep placement in wetland rice [72] and forest fertilization.

Storage. The shift from bagged to bulk transport and storage of prilled and granulated urea has called for warehouse designs in which large quantities of urea can be stored in bulk. These warehouses should be designed in such a way that the product suffers little degradation. Degradation may result from: (1) segregation of fines; (2) disintegration; and (3) absorption, loss, or migration of water.

Segregation of fines can be avoided through uniform product spreading during pouring. *Disintegration* can be minimized by:

1) Providing the product pouring system with a pouring height adjuster
2) Design of "product-friendly" reclaiming systems, because reclaiming the product by means of payloaders and tractor shovels invariably leads to product disintegration

Caking and subsequent product disintegration at unloading are known to result from water absorption. What is not commonly known,

however, is that excessive drying of the product during storage also leads to a higher caking tendency and that migration of water from warm product in the bulk of a pile to the cold surface leads to crust formation. Thus, attempts to decrease water absorption through refrigeration or air conditioning, dehumidification, or space heating may cause the air in the warehouse to become too dry or may result in too great a temperature difference between the product and the surrounding air. Instead, the warehouse (especially the roof) should be airtight and thoroughly insulated. The caking tendency of urea can be reduced by addition of small amounts of formaldehyde (up to 0.6 wt %) to the urea melt or by addition of surfactants to the solid product.

Transportation. Urea prills and granules are transported by bulk transport in trucks, ships, rail cars, etc. To withstand numerous and rapid loading and unloading operations, product for bulk transport should have a high initial physical stability. Great demands are made, especially on the shock resistance of the product, e.g., at seaport loading and unloading facilities. In addition, a number of "good housekeeping" rules should be adhered to:

1) Do not load or unload during rain
2) Make sure that the means of transport is clean and dry
3) Close the ship's hold when rain is imminent
4) Do not replace the air above the product or ventilate the holds
5) Cover the product (e.g., by polyethylene sheeting) during prolonged transport
6) Product should be spread rather then poured solely from one point to prevent dust coning due to segregation
7) Restrict the pouring height to avoid unnecessary disintegration

Liquid Fertilizer Transport. Liquid fertilizers are transported by tank cars, railway tanks, ships, and pipelines. Although liquid fertilizer is generally accepted as the most economic form to distribute, the solid form is still the most popular by far. Distribution of large quantities of liquid fertilizer requires a complex infrastructure and is limited at present to large farm units in developed countries. Transport and storage of UAN solutions in carbon steel lines and tanks require the addition of a corrosion inhibitor to the solution.

5. Quality Specifications and Analysis

Typical quality specifications for fertilizer-grade urea are summarized in Table 2. The capabilities of a modern urea plant are better than the typical trade data given in this table.

Table 2. Typical product specifications for fertilizer-grade urea

Specification	Prilled product	Granulated product
Nitrogen content, wt %	min. 46	min. 46
Biuret content, wt %	max. 1	max. 1
Water content, wt %	max. 0.3	max. 0.25
Crushing strength, bar	20 – 25	30 – 60
Shock resistance, wt %	min. 85	100
Product size		
1.0 – 2.4 mm, wt %	90 – 95	
1.6 – 4.0 mm, wt %		95
Bulk density (loose), kg/m^3	730	750 – 790

The total *nitrogen content* is usually determined by digesting urea with sulfuric acid toyield ammonium sulfate. The ammonia content is then determined by distillation and titration. Alternatively, the total N content may be determined by the Kjeldahl method or by using a method based on hydrolyzing urea with urease followed by titration of the ammonia formed.

The *water* content is usually determined with Karl Fischer reagent (→ Gas Production, Chap. 8.2.2.3.).

Biuret is determined by the formation of a violet-colored complex of biuret with copper(II) sulfate in an alkaline medium and subsequent measurement of the absorbance of the colored solution at 546 nm.

Crushing strength is defined as the force required per unit cross-sectional area of a granule to crush the granule or, if it is not crushed, the force at which it is deformed by 0.1 mm. A single granule is subjected to a force that is increased at a constant rate, the force at breakage (or at 0.1-mm deformation) being recorded.

The *shock resistance* of granules is defined as the weight percentage of a sample that is not crushed when subjected to a specified shock load. To determine shock resistance, a sample of prills or granules is shot against a metal plate

by means of compressed air under normalized conditions. The amount of nondamaged product that remains after the test is determined.

The *granulometry* of the product is measured by conventional sieve techniques.

6. Uses

Urea is used for soil and leaf fertilization (more than 90 % of the total use); in the manufacture of urea – formaldehyde resins; in melamine production; as a nutrient for ruminants (cattle feed); and in miscellaneous applications.

Soil and Leaf Fertilization. Worldwide, urea has become the most important nitrogenous fertilizer. Urea has the highest nitrogen content of all solid nitrogenous fertilizers; therefore, its transportation costs per tonne of nitrogen nutrient are lowest. Urea is highly soluble in water and thus very suitable for use in fertilizer solutions (e.g., "foliar feed" fertilizers). Urea is also used as a raw material for the production of compound fertilizers. Compound fertilizers may be produced by mixing in urea melts or urea solutions before shaping the compound fertilizers or by mixing solid urea prills or granules with other fertilizers (bulk blending). In the latter case, the product sizes must match to prevent segregation of the products during further handling.

Urea – Formaldehyde Resins (→Amino Resins, Chap. 7.1.). A significant proportion of urea production is used in the preparation of urea – formaldehyde resins. These synthetic resins are employed in the manufacture of adhesives, molding powders, varnishes, and foams. They are also used to impregnate paper, textiles, and leather.

Melamine Production. At present, nearly all melamine production is based on urea as a feedstock (→Melamine and Guanamines, Chap. 4.). Since ammonia is formed as a coproduct in melamine production from urea (see Chap. 1), integration of the urea and melamine production processes is beneficial.

Feed for Cattle and other Ruminants. Because of the activity of microorganisms in their cud, ruminants can metabolize certain nitrogen-containing compounds, such as urea, as protein substitutes. In the United States this capability is exploited on a large scale. In Western Europe, by contrast, not much urea is used in cattle feed.

Other Uses. On a smaller scale, urea is employed as a raw material or auxiliary in the pharmaceutical industry, the fermenting and brewing industries, and the petroleum industry. Urea can be used for the removal of NO_x from flue gases. Urea is also used as a solubilizing agent for proteins and starches, and as a deicing agent for airport runways.

7. Economic Aspects

The predicted growth in *demand* for urea until 1997 is slightly more than 3 % per year, bringing the total urea demand in 1997 to some 89×10^6 t/a. Most of the growth will occur in Asia, with China and India in the lead. A little more than 7 % of the worldwide demand for urea is from industry, in which Europe takes a leading role, ahead of North America and the industrialized countries of Asia.

The predicted growth in *capacity* up to 1997 will be around 1.5 % per year, resulting in a total installed capacity of some 100×10^6 t by 1997. Between 1994 and 1997, new plants will account for an increase in capacity of ca. 6.5×10^6 t, whereas closure of old plants will result in a reduction of the installed capacity by some 2×10^6 t. The world's capacity utilization can thus be calculated to be ca. 89 %.

Because of geopolitical changes during the early 1990s, different economic laws have become valid in the former Soviet Union and Eastern Europe, causing those countries to supply to the world market large amounts of prilled urea at prices far below the cost to many producers [e.g., sales prices, free on board (FOB) Black Sea $ 75 per tonne in 1993]. This situation is not expected to last long, although FOB prices at Black Sea ports will generally remain lower compared to other places. In the 1990s urea prices have shown large fluctuations. For instance, in 1994 – 1995 lows of $ 100 per tonne and highs of $ 250 per tonne have been reported. Predictions of future developments of urea prices are therefore highly speculative.

To cope with tough competition on the world market, producers have the tendency to build plants with very high single line capacities (2000 t/d or more), in which operating reliability is of extreme importance. Uninterrupted operating periods of more than one year are often achieved.

Furthermore, producers are increasingly shifting production facilities (both new plants and relocations) to places where natural gas is plentiful and cheap. Europe seems to have lost its competitive edge in export markets due to its expensive feedstocks.

The investment costs (in 10^6 \$) for a present state-of-the-art total-recycle urea plant are estimated to be:

1000-t/d plant (single line) 43
1500-t/d plant (single line) 52
2000-t/d plant (single line) 62

8. Urea Derivatives

Barbituric acids and derivatives, see →Hypnotics, Chap. 5.1.

8.1. Thermal Condensation Products of Urea

Thermolysis of urea gives biuret, triuret, and cyanuric acid, and in a special process, melamine is produced.

Biuret [*108-19-0*], imidodicarbonic diamide, $H_2NCONHCONH_2$, *mp* 193 °C, is produced by heating urea in inert hydrocarbons at 110–125 °C or in the melt at 127 °C [73], [74].

Triuret [*556-99-0*], diimidotricarbonic diamide, $H_2NCONHCONHCONH_2$, *mp* 231 °C, is produced by decomposing urea in a thin film at 120–125 °C [75]. It is also obtained by treating 2 mol of urea with 1 mol of phosgene in toluene at 70–80 °C [76], [77].

Cyanuric acid [*108-80-5*], 1,3,5-triazine-2,4,6 (1*H*,3*H*,5*H*)-trione (**1**), is formed on heating urea in the presence of zinc chloride, sulfuryl chloride, or chlorosulfuric acid [78].

Melamine [*108-78-1*], 1,3,5-triazine-2,4,6-triamine (**2**) is produced industrially from urea [79] (→Melamine and Guanamines, Chap. 4.).

8.2. Alkyl- and Arylureas

Most simple substituted alkylureas are crystalline products. Tetramethyl- and tetraethylurea and some cyclic ureas are liquids. Alkylated and arylated ureas are used in the production of plant protection agents, in pharmaceutical and dye chemistry, as plasticizers, and as stabilizers. Alkylureas and polyalkyleneureas are used as additives in the production of aminoplastics.

Various processes can be used for the production of substituted ureas, the most important of which are listed in Table 3.

Table 3. Production processes for substituted ureas

Starting materials	Product
Urea and amines	ureas substituted at one or both nitrogen atoms and cyclic ureas
Urea and tertiary alcohols	ureas substituted at one nitrogen atom
Phosgene and amines	ureas substituted at one nitrogen atom
Isocyanates and NH_3 or amines	ureas substituted at one or both nitrogen atoms
Carbamoyl chloride and NH_3 or amines	ureas substituted at one or both nitrogen atoms
Esters of carbonic or carbamic acids	ureas substituted at one or both nitrogen atoms
Urea and aldehydes or ketones	ureas substituted at one or both nitrogen atoms and cyclic ureas

8.2.1. Transamidation of Urea with Amines

The transamidation of urea with amines is one of the most important industrial production processes for substituted ureas. Monosubstituted

ureas are produced by condensation of urea with a sufficiently basic amine in a 1 : 1 molar ratio in the melt at 130 – 150 °C [80]. Symmetrically disubstituted ureas can be produced from 2 mol of amine and 1 mol of urea at 140 – 170 °C [81]. Instead of the amines, amine salts can also be reacted with urea in the melt or by prolonged boiling in aqueous solution [82].

Monomethylurea [*598-50-5*], $CH_3NHCONH_2$, *mp* 102 °C, is produced industrially by passing monomethylamine into a urea melt [83]. Monomethylurea is used for the synthesis of theobromine.

Phenylurea [*64-10-8*], $C_6H_5HNCONH_2$, *mp* 147 °C, can be produced by heating an aqueous solution of aniline hydrochloride and urea to its boiling point [84].

Symmetric *N,N′*-dimethylurea [*96-31-1*], $CH_3HNCONHCH_3$, *mp* 105 °C, is used for the synthesis of caffeine by the Traube method and for the production of formaldehyde-free easy-care finishing agents for textiles [84].

Hexamethylenediurea [*2188-09-2*], $H_2NCONH(CH_2)_6NHCONH_2$, is obtained by heating a mixture of hexamethylenediamine with an excess of urea at 130 – 140 °C, with elimination of ammonia [85], [86].

***N,N′*-Diphenylurea** [*102-07-8*], carbanilide, $C_6H_5HNCONHC_6H_5$, *mp* 238 °C, can be produced in high yields by heating 2 mol of aniline with 1 mol of urea in glacial acetic acid [86], [87].

Polyalkyleneureas can be obtained by treating di-, tri-, and tetraalkylenamines in concentrated aqueous solution with urea at ca. 110 °C. They are used, for example, to modify melamine – formaldehyde impregnating resins and binders for derived timber products. Examples of polyalkyleneureas include the following:

1,2-Ethylenediurea, $H_2NCONH-CH_2CH_2-HNCONH_2$, *mp* 198 °C
1,3-Propylenediurea, $H_2NCONH-CH_2CH_2CH_2-HNCONH_2$, *mp* 186 °C
Diethylenetriurea, $H_2NCONH-CH_2CH_2-N(CONH_2)-CH_2CH_2-HNCONH_2$, *mp* 215 °C
Dipropylenetriurea, $H_2NCONH-(CH_2)_3-N(CONH_2)-(CH_2)_3-HNCONH_2$
2-Hydroxypropylene-1,3-diurea, $H_2NCONH-CH_2CH(OH)-CH_2-HNCONH_2$, *mp* 147 °C

Cycloalkyleneureas. *2-Imidazolidinone* [*120-93-4*], ethyleneurea (**3**), *mp* 131 °C [88], [89]; *2-oxohexahydropyrimidine* [*65405-39-2*], propyleneurea (**4**), *mp* 260 – 265 °C [90]; and *2-oxo-5-hydroxyhexahydropyrimidine*, 5-hydroxypropyleneurea (**5**), are produced industrially in the melt above 180 °C, preferably at 200 – 230 °C, by condensation of 1,2-ethylenediamine or 1,3-propylenediamine with urea and elimination of ammonia. These cycloalkyleneureas are used in the form of their *N,N′*-dihydroxymethyl compounds for easy-care finishes for cellulose-containing textiles [91].

8.2.2. Alkylation of Urea with Tertiary Alcohols

Urea can be alkylated with tertiary alcohols in the presence of sulfuric acid [92], [93].

***tert*-Butylurea,** $(CH_3)_3CHNCONH_2$, *mp* 182 °C, is produced by treating urea with 2 mol of *tert*-butanol in the presence of ca. 2 mol of concentrated sulfuric acid at 20 – 25 °C with ice cooling [92–94].

8.2.3. Phosgenation of Amines

Symmetrically disubstituted ureas are produced in good yields by passing phosgene into solutions of amines in aromatic hydrocarbons [95]. In some cases, aqueous solutions or suspensions of amines can also be reacted with

phosgenes [96]. The phosgenation of mixed aliphatic – aromatic amines is carried out industrially in the presence of sodium hydroxide at 40 – 60 °C [97]. For the production of substantive dyes, aminosulfone or aminocarboxylic acid groups are bonded by means of phosgenation [98]

$$2\,RNH_2 + COCl_2 \rightarrow RNH-CO-NHR + 2\,HCl$$

Tetramethylurea [*632-22-4*], $(CH_3)_2NCON(CH_3)_2$, *bp* 156.5 °C, is produced from dimethylamine and phosgene and is used as an aprotic solvent [99].

Asymmetric Diphenylurea, $(C_6H_5)_2NCONH_2$, *mp* 189 °C, is produced from diphenylamine, phosgene, and ammonia:

$$COCl_2 + (C_6H_5)_2NH + 3\,NH_3 \rightarrow (C_6H_5)_2NCONH_2 + 2\,NH_4Cl$$

Symmetric dimethyldiphenylurea, *mp* 121 – 127 °C, is obtained by treating phosgene with monomethylaniline and sodium hydroxide.

Symmetric dialkyldiarylureas are used under the name Centralite as plasticizers and stabilizers for nitrocellulose and propellants [97].

8.2.4. Reaction of Amines with Cyanates (Salts)

The salts of aliphatic or aromatic amines react with potassium cyanate at 20 – 60 °C to give substituted ureas in high yields [100], [101].

$$R-NH_2\cdot HX + KNCO + H_2O \rightarrow R-HNCONH_2 + KX + OH^-$$

4-Ethoxyphenylurea [*150-69-6*] (dulcin) is produced from potassium cyanate and *p*-phenetidine hydrochloride in aqueous solution at room temperature [100]. This production method can be applied to aminosulfonic and aminocarboxylic acids, whereby the betaine-like salts formed by these acids react with potassium cyanate to give ureas that are substituted at only one NH_2 group [101]. Sulfonamides react with potassium cyanate to give potassium salts of the corresponding sulfonylureas, from which the sulfonylureas are obtained by acidification [102]:

$$RSO_2NH_2 + KNCO \rightarrow RSO_2N^-CONH_2\,K^+ \rightarrow RSO_2HNCONH_2$$

8.2.5. Reaction with Isocyanates

Symmetrically disubstituted ureas can also be produced from isocyanates by prolonged heating in aqueous solution [103], [104]:

$$RNCO \xrightarrow{H_2O} RHNCOOH \xrightarrow{RNCO} RHNCONHR + CO_2$$

When ammonia or primary or secondary amines are reacted with isocyanates, the corresponding substituted ureas are obtained in almost quantitative yield [104–106]. This process is particularly suitable for the production of unsymmetrically substituted ureas [105], [106].

8.2.6. Acylation of Ammonia or Amines with Carbamoyl Chlorides

Ammonia and primary or secondary amines react with carbamoyl chlorides to give the corresponding urea derivatives in good yields [107].

Tetraphenylurea, $(C_6H_5)_2NCON(C_6H_5)_2$, [108] is obtained in quantitative yield by heating diphenylcarbamoyl chloride with diphenylamine.

8.2.7. Aminolysis of Esters of Carbonic and Carbamic Acids

Esters of carbonic and carbamic acids (carbonates and carbamates) react with amines at ele-

vated temperatures to give symmetrically disubstituted ureas [109–112].

8.3. Reaction of Urea and Its Derivatives with Aldehydes

8.3.1. α-Hydroxyalkylureas

The industrial production of α-hydroxyalkylureas is limited to the addition of formaldehyde or glyoxal to urea, monoalkylureas, symmetrical dialkylureas, and cyclic ureas. It involves acid- or base-catalyzed additions that are generally equilibrium reactions [113–130].

Urea can bond with up to 4 mol of formaldehyde. However, only monohydroxymethyl- and *N,N′*-dihydroxymethylurea can be isolated in pure form [131], [132]. Tri- and tetrahydroxymethylureas are formed only as nonisolable intermediates, for example, in the synthesis of trimethoxymethylurea (**6**), [133], [134]; *N,N′*-dialkoxymethyl-4-oxomethyltetrahydro-1,3,5-oxadiazine (**7**) [135], [136]; and *N,N′*-dihydroxymethyl-2-oxo-5-alkyltetrahydro-1,3,5-triazines (**8**) [137–140].

6 **7** **8**

R = Alkoxymethyl
R^1 = Hydroxymethyl
R^2 = Alkyl

***N,N′*-Dihydroxymethylurea** [*140-95-4*], $HOCH_2HNCONHCH_2OH$ [131], [132] is produced industrially by charging 2 mol of formaldehyde per mole of urea to a stirred vessel. The solution is neutralized with triethanolamine. Urea is added with cooling, and the temperature must not exceed 40 °C in this slightly exothermic reaction. After a few hours the reaction mixture is cooled to room temperature and dihydroxymethylurea crystallizes out. The product is dried in a spray-drying tower.

Hydroxymethyl derivatives of cyclic ureas can be produced by reaction of these substances with formaldehyde in an alkaline medium [141].

9 **10** **11** **12** **13** **14** **15**

Hydroxymethyl derivatives of urea and cyclic ureas (**9**)–(**15**) are used in easy-care finishes for textiles [91].

The addition of higher aldehydes to urea, mono- and symmetrically disubstituted ureas, and cyclic ureas generally gives unstable α-hydroxyalkyl compounds. Electron-withdrawing and electron-donating substituents next to the α-hydroxyalkyl group affect the stability of these compounds and also their ability to undergo condensations.

16 **17** **18**

For example, the chloral – urea derivatives (**16**) exhibit considerable differences in reactivity compared with the *N*-hydroxymethyl (**17**) and *N*-α-hydroxyethyl compounds (**18**). These differences are exemplified by a decrease in the H-acidity of the OH groups [142]. Chloral compounds (**16**) can form alkali-metal salts, whereas the corresponding salts of *N*-hydroxymethyl (**17**) and *N*-α-hydroxyethyl compounds (**18**) are

unknown. Condensation of chloral compounds with nucleophiles is possible only under extreme reaction conditions. However, N-α-hydroxyethyl compounds can be converted smoothly with alcohol into N-α-alkoxyethyl compounds in basic and sometimes even in neutral media. The reactivity of N-hydroxymethyl compounds lies between that of the chloral and N-α-hydroxyethyl compounds. The 4-hydroxycycloalkyleneureas (cyclic N-hemiacetals), which are obtained by treating suitable aldehydes with ureas, are stable. For example, 2-oxo-4,5-dihydroxyimidazolidines are formed by cyclization of urea, or its mono- or symmetrically disubstituted derivatives, with glyoxal [143–145]:

***N,N′*-Dihydroxymethyl-2-oxo-4,5-dihydroxyimidazolidine** (**20**) is produced by hydroxymethylation of 4,5-dihydroxy-2-oxoimidazolidine (**19**) in weakly acidic to weakly alkaline aqueous solution or, more elegantly, by direct reaction of urea with glyoxal and formaldehyde in the appropriate molar ratio in weakly acidic to neutral solution at 40 – 80 °C, sometimes in the presence of catalytically active buffers [130].

Compound **20** and its derivative in which the OH groups are partly acetalized with methanol are used as formaldehyde-free cross-linking agents for easy-care finishes for cellulose-containing textiles.

2-Oxo-4-hydroxyhexahydropyrimidines also belong to the group of α-hydroxyalkylureas. These compounds can be produced industrially by cyclocondensation of urea with active enolizable aldehydes (see Section 8.3.4).

8.3.2. α-Alkoxyalkylureas

Condensation of N-hydroxymethylureas with alcohols to give N-alkoxymethylureas (ureidoalkylation of alcohols) is of great industrial importance. Pure hydroxymethylureas and an excess of alcohol are reacted in the presence of catalytic amounts of acid. The nature and quantity of the acid catalyst depend on the reactivity of the N-hydroxymethyl compound, its stability to hydrolysis, and the formation of byproducts and polycondensation products. At elevated temperature the reaction can be carried out under weakly acidic conditions, whereby the equilibrium position must be adjusted by variation of the concentration and the molar ratios [91], [146], [147]. Sometimes, ureidomethylation of alcohols is better at room temperature in the presence of strong acids.

The alcohol-modified urea – formaldehyde condensation products are used as resins for heat- or acid-curing coatings. Besides the water-soluble or almost solvent-free resins, which are becoming increasingly important for environmental reasons, a wide range of aminoplastic resins for coatings exist that are readily soluble in common paint solvents. To convert urea – formaldehyde resins to resins that are soluble in organic solvents, the highly polar N-hydroxymethyl groups obtained in the initial reaction between urea and formaldehyde are acetalized with alcohols, mainly butanol and isobutanol, as well as ethanol and methanol or their mixtures.

The alcohol-modified urea – formaldehyde resins are produced industrially by passing aliphatic alcohols into aqueous solutions of urea and formaldehyde or solutions of hydroxymethylated ureas in the presence of small quantities of acid at 90 – 100 °C so that the water formed and excess alcohol distill off. The molar ratios vary between 2 and 4 mol of formaldehyde and 2 and 5 mol of alcohol per mole of urea. The process is carried out in a reactor equipped with an adequately dimensioned heat exchanger, a vacuum pump, a distillation column, and for alcohols that are sparingly soluble in water, a water separator.

Some *4-hydroxycycloalkyleneureas* are so reactive that they can be converted into the N-α-alkoxy compounds (**21**), (**22**) even in a neutral medium by heating with alcohol [148]:

21

22

To shift the equilibrium in the N-α-ureidoalkylation of alcohols in the direction of the N-α-alkoxyalkyl compounds, the water formed during the reaction must be removed. In industrial production processes an aprotic entrainer (e.g., an aromatic) is used. In the ureidomethylation of alcohols that are immiscible or sparingly miscible with water, an excess of alcohol is used and water is removed by azeotropic distillation.

Higher-boiling alcohols can also be ureidomethylated by transacetalization of the N-methoxymethyl compounds.

Polymerizable compounds are obtained by ureidoalkylation of unsaturated alcohols (e.g., allyl alcohol [149], [150]). Tetraallyloxymethyltetrahydroimidazo[4,5-*d*]imidazole-2,5(1*H*,3*H*)-dione (**23**) has achieved importance as a polymerizable coating component [151], [152]:

23

8.3.3. α,α'-Alkyleneureas

α,α'-Alkyleneureas are obtained by condensation of urea or its derivatives with aldehydes in a weakly acidic medium. The aldehyde group first adds to the urea to form an α-hydroxyalkylurea, which then reacts with a second molecule of urea or with another α-hydroxyalkylurea to give linear or branched α,α'-alkyleneureas:

Reaction of equimolar quantities of urea and formaldehyde in acidic solution gives polymethyleneureas as a result of stepwise ureidomethylations:

KADOWAKI obtained polymethyleneureas containing up to five urea groups joined by methylene bridges by means of a stepwise synthesis [135]. Because of their extreme insolubility, no higher polymethyleneureas have yet been isolated. Polymethyleneureas are used as slow-release nitrogen fertilizers, for example.

Isobutylidenediurea (**24**), which is sparingly soluble in water, is obtained by condensation of urea with isobutyraldehyde in a molar ratio of 2 : 1 in a weakly acidic medium:

24

Isobutylidenediurea is also a slow-release nitrogen fertilizer used in various special fertil-

izer formulations. Isobutylidenediurea is produced by a continuous process. According to a patent published by Mitsubishi Chemical Industries [153], urea is charged continuously with a screw feed via a belt weigher and is reacted with a stoichiometric quantity of isobutyraldehyde in the presence of semiconcentrated sulfuric acid in a mixer. In the last section of the mixer the reaction product is neutralized by injecting dilute aqueous potassium hydroxide solution. The product is dried by using plate driers and processed by sieving, filtering, and grinding.

8.3.4. Cyclic Urea – Aldehyde Condensation Products

Almost all cyclizations of urea and its derivatives with aldehydes involve an α- or a vinylogous ureidoalkylation [113–115], [146]. If the urea bears a nucleophilic substituent on the second nitrogen atom, cyclocondensation occurs [154]. Saturated and unsaturated cyclic ureas with five, six, seven, or eight ring atoms, bicyclic and polycyclic heterocycles (with both uncondensed rings and rings anellated in the 1,2- or 1,3-position), and spiro compounds can be produced this way [154], [155].

Industrially important reactions are those of urea with formaldehyde, acetaldehyde, isobutyraldehyde, and their mixtures. Treatment of urea with formaldehyde in a molar ratio of 1 : $\geq$4 gives an equilibrium mixture of hydroxymethyl derivatives. On ureidomethylation of a hydroxymethyl group bonded to the second nitrogen atom of the urea, cyclocondensation to hydroxymethylated 4-oxotetrahydro-1,3,5-oxadiazines (**25**) occurs [135], [136].

4-Oxo-3,5-dialkoxymethyltetrahydro-1,3,5-oxadiazines are used as cross-linking agents for easy-care finishing of textiles. These compounds can be obtained directly by condensation of urea with formaldehyde and alcohols [135], [136]:

The hydroxymethyl and methoxymethyl derivatives of *2-oxo-5-alkylhexahydro-1,3,5-triazines* have achieved importance as cross-linking agents for easy-care finishing of cellulose-containing fabrics. These compounds are obtained by cyclizing ureidomethylation of urea with formaldehyde and a primary amine [137–140], [154]:

Bicyclic Ureas. 4,5-Dihydroxy- or 4,5-dialkoxyimidazolidin-2-ones can be converted into bicyclic ureas, such as *tetrahydroimidazo*[*4,5-d*]*-imidazole-2,5*(*1H,3H*)*-dione* (**26**), by means of a double α-ureidoalkylation with urea:

26

27

Tetrahydroimidazo[4,5-*d*]imidazole-2,5(1*H*, 3*H*)-dione [*496-46-8*], acetylenediurea (**26**), can be obtained directly by condensation of glyoxal with excess urea in an acidic medium [156], [157]. A solution of urea is acidified to pH <3 with sulfuric acid, and a 40 % glyoxal solution is added slowly. At the end of the reaction the molar ratio of glyoxal to urea is adjusted to at least 1 : 2.5. Reaction temperature should not exceed 70 °C. The precipitated product is neutralized by decantation and stirring with water.

In the form of its tetrahydroxymethyl derivative (**15**) the product has achieved importance as a cross-linking agent in easy-care textile finishes [158]. The saturated and unsaturated *N*-alkoxymethyl compounds (**23**) are used as cross-linking agents in the paint and coating industry.

The tetrachloro compound (**27**) is used as a chlorine-transfer agent for mild chlorination reactions and as a bleaching agent for textiles [159–161].

The synthetic possibilities for cyclizing α-ureidoalkylations with compounds containing enolizable carbonyl groups are manifold. Aldehydes and ketones are particularly important because they react not only as nucleophiles but also as carbonyl components in these cyclocondensations. Under mild conditions (i.e., in weakly acidic media), aliphatic and aromatic aldehydes generally react only as carbonyl components in reactions with urea and its derivatives, giving linear or branched condensation products. In a more strongly acidic medium and at elevated temperature, however, an α-ureidoalkylation at nucleophilic α-carbon atom in the aldehyde occurs. (see right column)

In the cyclocondensation of urea or its mono- or symmetrically disubstituted derivatives with aldehydes, which have at least one activated hydrogen in α-position to the carbonyl group, 2-oxo-4-hydroxyhexahydropyrimidines (**29**) are formed in the presence of an acid [113], [154], [162], [163]. Symmetrical di-α-hydroxyalkyl compounds (**28**) and poly-α-alkyleneureas are formed as intermediates. They all contain the groups necessary for cyclocondensation involving an α-ureidoalkylation, i.e., the NH component, 1 mol of aldehyde as the carbonyl component, and the second mole of aldehyde as the nucleophilic component with activated α-hydrogen. In cyclocondensation, a bond is formed between the nucleophilic α-carbon atom of one α-hydroxyalkyl group and the carbon α to the urea nitrogen in the second α-hydroxyalkyl group to give 2-oxo-4-hydroxyhexahydropyrimidines (**29**).

Preparation of 2-Oxo-4-hydroxy-5,5-dimethyl-6-isopropylhexahydropyrimidine (*mp* 220–222 °C). One liter of a 30 % aqueous urea solution (5 mol) is treated with 100 mL of 50 % sulfuric acid in a stirred tank reactor with reflux cooling. Then, 10 mol isobutyraldehyde is added with stirring. After being heated at 85 °C for 2 h, the product is filtered and washed with water.

If these cyclocondensations are carried out in the presence of alcohols, 2-oxo-4-alkoxyhexahydropyrimidines (**30**) are formed [163], [164].

These cyclocondensations can also be carried out between urea and two different aldehydes, at least one of which must have an enolizable carbonyl group. For example, the cyclocondensation of 1 mol of urea with 1 mol of formaldehyde and 1 mol of isobutyraldehyde in the presence of an acid gives 2-oxo-4-hydroxy-5,5-dimethylhexahydropyrimidine (**31**) [164]

The 2-oxo-4-hydroxy-5,5-dimethylhexahydropyrimidines are cyclic *N*-hemiacetals, whose OH groups can undergo nucleophilic substitutions similar to those undergone by *N*-hydroxymethylureas. 2-Oxo-4-hydroxy- and 2-oxo-4-alkoxy-5,5-dialkylhexahydropyrimidines are used in the form of their *N,N′*-dihydroxymethyl compounds in noncrease finishes for cellulose-containing textiles [91], [165].

Preparation of *N,N′*-Dihydroxymethyl-2-oxo-4-hydroxy(methoxy)-5,5-dimethylhexahydropyrimidine. Urea is treated with formaldehyde in the molar ratio 1 : 1 at pH >9 and 50 – 60 °C in the presence of an excess of methanol. Isobutyraldehyde is added in the presence of a strong mineral acid to bring about cyclocondensation. The reaction mixture is rendered alkaline, and hydroxymethylation is carried out with formaldehyde.

2-Oxo-4-hydroxyhexahydropyrimidines (**32**), which are not or only mono-substituted in the 5-position, react with ureas to give 2-oxo-4-ureidohexahydropyrimidines (**32**).

2-Oxo-4-ureido-6-methylhexahydropyrimidine [*1129-42-6*], crotonylenediurea (**33**), is obtained either by condensation of urea with crotonaldehyde in the presence of acid [166] or by the industrially more straightforward route involving condensation of urea with acetaldehyde in the molar ratio 1 : 1 in the presence of acid [167], [168]. 2,7-Dioxo-4,5-dimethyldecahydropyrimido[4,5-*d*]pyrimidine is formed as a byproduct in the second route [168–170].

2-Oxo-4-ureido-6-methylhexahydropyrimidine is produced industrially in a continuous process employing a stirred tank cascade. A 70 % urea solution is treated with acetaldehyde at a molar ratio of 1 : 1 in the presence of a catalytic quantity of 75 % sulfuric acid. The exothermic reaction is kept at 38 – 60 °C by controlled cooling. The pH is initially kept above 3 and in the final reactors below 2 by addition of sulfuric acid. Average residence time in the cascade is 40 min. In the last stirred tank, the reaction mixture is neutralized with aqueous potassium hydroxide solution. Drying is carried out in a spray tower.

2-Oxo-4-ureido-6-methylhexahydropyrimidine is used as a slow-release nitrogen fertilizer [171]. This fertilizer is characterized by its extreme insolubility in water and is therefore not washed out of the soil by rain or irrigation. It decomposes as a result of acid hydrolysis induced by humic acids during the growth period of plants, bringing about mineralization of the nitrogen it contains.

2-Oxo-4-hydroxy-5,5-dimethylhexahydropyrimidyl-*N,N′*-bisneopentals can be produced from urea, formaldehyde, and isobutyraldehyde in acid-catalyzed cyclo- and linear condensations. These bisneopentals react further according to a Claisen – Tishchenko reaction to give soft and hard resins with good light stability for the paint and coatings industry, depending on the molar ratios of the starting materials [172], [173].

1. History [1]

In 1801, MANUEL DEL RIO discovered vanadium in Mexican lead vanadate ore. In 1831, SEFTSTRÖM detected the element in converter slags from certain iron ores, and named it after the Norse goddess of beauty, Vanadis.

Vanadium metal was first produced in powder form by ROSCOE in 1867 – 1869 by reduction of vanadium dichloride with hydrogen. MARDEN and RICH obtained ductile vanadium by reducing vanadium pentoxide, V_2O_5, with calcium metal.

The first major application of vanadium was in 1903 in England, where a vanadium-alloyed steel was produced on an 18 t scale [2]. In 1905 HENRY FORD recognized the advantages of vanadium steel and promoted its use in automobile construction. Today vanadium is of major importance as an alloying component in steel and titanium alloys and as a catalyst for chemical reactions.

2. Properties

Vanadium [*7440-62-2*], V, atomic number 23, has two stable isotopes: ^{51}V (99.75 %) and ^{50}V (0.25 %). Unstable isotopes of relative atomic mass 48, 49, and 52 have half-lifes ranging from 4 min to 600 d. The electronic configuration is $1s^2\,2s^2p^6\,3s^2p^6d^3\,4s^2$. Vanadium is steel gray with a bluish tinge. It is ductile, and can be forged and rolled at ambient temperature.

Vanadium, together with niobium and tantalum, belongs to group 5 of the periodic table. It has a high melting point and good corrosion resistance at low temperature.

Physical Properties. The most important physical properties of vanadium are listed in the following [1], [3–6]:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_367

Relative atomic mass	50.9415
Crystal structure	body-centered cubic
Lattice constant a	0.30238 nm
Density	6.11 g/m^3

Heat of vaporization	465.9 kJ mol^{-1}
Linear coefficient of expansion	
at 20 – 200 °C	7.88×10^{-6}
at 20 – 500 °C	9.6×10^{-6}
at 20 – 900 °C	10.4×10^{-6}
at 20 – 1100 °C	10.9×10^{-6}
Specific electrical resistivity at 20 °C	24.8×10^{-6} Ω cm
Temperature coefficient for 0 – 100 °C	0.0034 μΩ cm K^{-1}
Thermal conductivity	
at 100 °C	0.31 J cm^{-1} K^{-1} s^{-1}
at 500 °C	0.37 J cm^{-1} K^{-1} s^{-1}
Superconductivity, transition temperature	5.13 K
Capture cross section for thermal neutrons	4.8 barn

Mechanical Properties. The mechanical properties of vanadium are strongly dependent on purity and hence on the production method used. In particular, the elements O, H, N, and C increase the hardness and tensile strength and decrease the ductility (elongation) [7]. The most important mechanical properties are listed in Table 1 [3], [4], [7].

Table 1. Mechanical properties of vanadium metal

	Commercial purity	High purity
Tensile strength σ_B, N/mm	245 – 450	180
Extension, %	10 – 15	40
Vickers hardness HV 10, N/mm	80 – 150	60 – 70
Modulus of elasticity, N/mm	137 000 – 147 000	
Poisson's ratio	0.35	

Chemical Properties. Vanadium is stable in air below 250 °C. On prolonged storage the surface becomes bluish-gray to brownish-black, and significant oxidation takes place in air above 300 °C. Vanadium absorbs hydrogen in interstitial lattice sites at elevated temperatures (up to 500 °C). The metal becomes brittle and can easily be powdered. This hydrogen is liberated on heating to 600 – 700 °C in vacuum. At low temperature, a hydride phase exists in the V – H system [7]. Vanadium reacts with nitrogen at > 800 °C to form vanadium nitrides. It has a high affinity for carbon, forming carbides at 800 – 1000 °C. Data on the solubility of O, N, H, and C in vanadium and the reactions that occur with these elements can be found in [7], [8].

In its compounds, vanadium exhibits the oxidation state II, III, IV, or V. It is relatively stable towards dilute sulfuric, hydrochloric, and phosphoric acids, but is dissolved by nitric and hydrofluoric acids. Its corrosion resistance towards tap water is good, and towards seawater moderate to good, but pitting does not occur. Vanadium is resistant to 10 % sodium hydroxide solution, but is attacked by a hot solution of potassium hydroxide [1], [3], [4], [9], [10]. Vanadium and some vanadium alloys have good corrosion resistance towards molten low-melting metals and alloys, especially alkali metals, which are used in nuclear reactors as coolants and heat-exchange media [11].

3. Occurrence

Vanadium is present in the earth's crust at a mean concentration of 150 g/t, and is therefore one of the more common metals. It is more abundant than copper and nickel, and of similar abundance to zinc. Vanadium forms several minerals, of which the most important are listed in Table 2 [12], [13].

In the early 1900s, vanadium was obtained almost exclusively from Peruvian patronite. As these deposits became exhausted, descloizite ores were mined in southern Africa, Namibia, and Zambia.

After World War II, the continental sedimentary uranium- and vanadium-containing carnotite deposits of the Colorado Plateau and the marine sedimentary vanadium-bearing phosphate deposits of Idaho became important. There

Table 2. Principal vanadium minerals [12], [13]

Mineral and chemical formula		Vanadium content, %	V_2O_5 content, %	Occurrence
Roscoelite	$[KV_2(OH)_2/AlSi_3O_{10}]$	11.2 – 14.0	20 – 25	in uranium – vanadium ores; e.g., Colorado Plateau, United States
Montroseite	(V, Fe)OOH	45.4	81.0	
Carnotite	$K_2[(UO_2)_2/V_2O_8] \cdot 3\,H_2O$	10.3	18.3	
Tyuyamunite	$Ca[(UO_2)_2/V_2O_8] \cdot 5-8\,H_2O$	11.1	19.8	
Francevillite	$(Ba, Pb)[(UO_2)_2/V_2O_8] \cdot 5\,H_2O$	9.9	17.7	
Corvusite	$V_2^{4+} \cdot V_{12}^{5+}O_{34} \cdot n\,H_2O$	40.8	72.8	
Vanadinite	$Pb_2[Cl/(VO_4)_3]$	10.2	18.2	in Pb, Zn, Cu vanadate ores; e.g., Otavi Mountains, Namibia
Descloizite	$Pb(Zn, Cu)[OH/VO_4]$	12.7	22.7	
Mottramite	$Pb(Cu, Zn)[OH/VO_4]$	10.5	18.8	
Patronite	VS_4 or V_2O_5	16.8	ca. 30	in asphaltites; e.g., Mina Ragra, Peru
Magnetite∗	$Fe_2^{2+} \cdot Fe^{3+}O^{4-}$	$< 0.5 - 1.5$	$< 1.2 - 2.7$	in titanomagnetite ores; e.g., Bushveld, Republic of South Africa
		max. 2.8	max. 5.0	

∗ Several varieties exist in which there is partial replacement of Fe^{3+} by V, Ti, Al, and Cr, and of Fe^{2+} by Ti, Mg, Mn, and other elements. The vanadium- and titanium-containing magnetites are generally referred to as titanomagnetites.

are also uranium – vanadium reserves in Yeellirie, Western Australia, and in the Ferghana Basin the Kirghiz, Tadzhik, and Uzbek Republics [13].

Vanadium production greatly increased from the mid-1950s with the mining and processing of titanomagnetites. This type of raw material can be used directly for vanadium extraction, or it can be employed to obtain vanadium-containing pig iron from which an oxidation slag highly enriched in vanadium is produced. This development began in Finland, followed by South Africa and smaller producers in Norway and Chile. Titanomagnetites have also been mined in the former Soviet Union and China in large quantities since the early 1960s and 1970s, respectively. The vanadium-bearing titanomagnetite deposits are of magmatogenic origin, and occur in many parts of the world. The most important reserves mined today include the Bushveld deposit in South Africa, Katschkanor in the Urals of Russia, Lanshan and Chienshan in the Sichwan province of China, and a deposit in New Zealand. The titanomagnetites of the Urals and in the Sichwan province are palaeozoic complexes.

The mines at Otanmäki and Mustavaara in Finland and Rødsand in Norway were shut down during the 1980s.

Production of lead – zinc vanadates in Namibia had been discontinued by the end of the 1970s.

Since the 1980s, a new type of secondary raw materials has gained importance, i.e., residues of mineral oil processing. Most crude oils contain vanadium in amounts ranging from ca. 10 ppm (Middle East) to 1400 ppm (Central America). In petrochemical refining, vanadium is retained in boiler residues and fly ashes from incineration, with vanadium contents between a few percent and 40 %. The total amounts greatly exceed current world consumption.

Noteworthy is an aqueous emulsion of a highly viscous crude from the Orinoco basin in Venezuela (Orimulsion) whose combustion yields fly ashes containing 10 % vanadium.

With environmental legislation becoming stricter, emission and deposition of these residues will be drastically reduced so that they will have increasingly to be processed.

Table 3. Vanadium production as a byproduct

Raw material	Coupled product	Vanadium byproduct
Titanomagnetites	iron/steel	vanadium slag
Mineral oils	energy/petrochemicals	fly ashes boiler residues
Uranium – vanadium ores	uranium	petrochemical residue
Bauxite	alumina	vanadium salt
Phosphates	phosphorus	vanadium-containing Fe – P salamander
Lead vanadates	lead, zinc	vanadium slag

Other, less important vanadium sources are: vanadium-containing waste salts from bauxite

production, and spent catalysts from the chemical and petrochemical industries. The extraction of vanadium from currently available raw material sources (except direct processing of titanomagnetite) is always coupled with the production of other metals or energy. The most important sources are shown in Table 3.

Resources and Production. Known and estimated mineral reserves are listed in Table 4.

In this table the vanadium containing carbonitic shells (very low concentration) and the petroleum ashes/residues are not included, although these oils contain tremendous amounts of vanadium.

Assessment of world reserves by studying the geology of deposits suggests that it will be possible to discover further workable deposits in the region of the widely distributed titanomagnetites in the old shields. The Indian shield in the Singhbum (Bihar) and Magurbhanj (Orissa) regions, the Australian shield in Western Australia, the Canadian shield in Quebec and Ontario, and the Finno-Scandinavian shield all show great promise. However, little is so far known about the Brazilian shield. The enormous vanadium reserves in the titanomagnetites cannot yet be even approximately quantified.

The world production of vanadium by country is listed in Table 5 [14].

Comparison of Tables 4 and 5 shows that the largest producers, the Republic of South Africa and Russia, have also the largest mineral reserves. The next two producing countries China and the United States have comparatively small reserves of such origin.

Details of the Most Important Deposits. The Bushveld deposit in South Africa is an oval, bowl-shaped complex in a magmatic layer extending over an area of 65 000 km^2. The ores were deposited in the following order: chromite, platinum ores, vanadium-containing titanomagnetites, and tin ores. In all, 21 magnetite layers have been found in the main and upper zones of this deposit. The titanomagnetites have the following chemical composition (%):

Fe	55.8 – 57.5	Cr_2O_3	0.13 – 0.45
V_2O_5	1.4 – 1.6	Al_2O_3	2.5 – 3.5
TiO_2	12.2 – 13.9	SiO_2	0.9 – 1.5

The V_2O_5 content can be as high as 2.4 % in exceptional cases.

Production by Highveld Steel & Vanadium is based on ore containing 1.6 % V_2O_5 from the Mapochs mine, situated 90 km NNE of Middleburg. The reserves contain 200×10^6 t ore. Mining is by the open pit method, and the maximum ore production capacity is 8000 t/d [13].

Other South African titanomagnetite deposits include the Kennedy's Vale mine, with a production capacity of 6000 t/d (though not currently producing) and two mines near Brits, each with a production capacity of 5000 – 6000 t/d.

There are a number of lead vanadate deposits in the Otavi Mountains in Namibia. Mount Aukas, near Grootfontein, has deposits of 2×10^6 t ore containing 15 % Zn, 4 % Pb, and 0.5 % V_2O_5. Deep mining has been discontinued since 1978. The mined ore, which was processed by flotation, yielded the following products: lead sulfide concentrate, zinc sulfide concentrate, willemite concentrate, cerussite concentrate, and a vanadium concentrate containing 17 % V_2O_5, 43 % Pb, and 17 % Zn.

The titanomagnetite deposits at Otanmäki and Mustavaara in Finland had reserves of 15×10^6 t ore containing 35 – 40 % Fe, 13 % TiO_2, and 0.45 V_2O_5, and 40×10^6 t ore containing 17 % Fe, 3.1 % TiO_2, and 0.36 %V_2O_5 [14]. The production capacity of the Otanmäki deep mine was ca. 1×10^6 t/a ore. Magnetite containing 69 % Fe, 2.5 % TiO_2, and 1.07 % V_2O_5 together with ilmenite and pyrite were obtained by magnetic separation and flotation. Both mines were closed in the 1980s.

The Colorado Plateau in the United States contains the main mining area of the Uravan mineral belt, > 1100 km long, in SW Colorado and SE Utah. This belt contains irregular lenticular ore bodies, normally < 3000 t, with 0.2 – 0.3 % U_3O_8 and 0.85 – 1.4 % V_2O_5. The oxidation region contains the minerals carnotite, tyuyamunite, montroseite, and pascoite, and the unoxidized region contains the minerals coffinite, pitchblende, and corvusite. These ores are extracted in small deep mine workings which produce ca. 0.4×10^6 t/a ore.

Table 4. Estimate of the world reserves and reserve base of vanadium in thousand tonnes of vanadium content (percentage given in parentheses)

Geographic area	Reserves		Estimated reserves
	1985	1990	1985

4. Processing of the Raw Materials to Vanadium Compounds

The raw materials used today include the titanomagnetite ores and their concentrates, which are sometimes processed directly, vanadium slags derived from the ores, oil combustion residues, residues from the hydrodemetallization (HDM) process, and spent catalysts (secondary raw materials). A summary of the processing routes is given in Figure 1.

4.1. Iron Ores and Titanomagnetites as Raw Materials

Production of Vanadium Slags. The titanomagnetite ore in lump form, containing ca. 1.51 – 1.7 % V_2O_5 (Mapoch mine in South Africa), is first prereduced by coal at ca. 1000 °C in directly heated rotary kilns. A further reduction is then performed in an electric arc furnace to obtain a pig iron which contains ca. 1.4 % V_2O_5. The slag that is also formed contains ca. 30 % TiO_2, and this is deposited on slag heaps. In a heat resistant shaking ladle the molten pig iron is oxidized with oxygen lances, causing the vanadium to be transferred to the slag. The vanadium slag contains vanadium in the form of a water-insoluble trivalent iron spinel, $FeO \cdot V_2O_3$, at a concentration corresponding to ca. 25 % V_2O_5. This slag is the world's principal raw material for vanadium production [16].

The largest slag and vanadium producer in the western world is South Africa (see Table 5), most of whose production is by the Highveld Steel and Vanadium Corp. [13]. Second largest producer is the Nizhny Tagil metallurgical plant in Russia; the slag contains ca. 12 – 18 % V_2O_5. Another producer of vanadium slag is the Pannang steelworks in Panzihua, China.

Vanadium slags were produced experimentally by W. L. Goodwin and W. P. Firth in 1919, but the basic industrial process was developed by R. von Setz, and was first used by the Spigerverk plant in Oslo in the early 1930s. The process was then mainly used in conjunction with the Thomas process. The pig iron from the blast furnace was not directly converted to Thomas steel with addition of lime in the usual way. Instead, the vanadium was oxi-

Figure 1. Treatment of vanadium raw materials [15]

dized completely or partially before lime addition. As vanadium has a high affinity for oxygen, it was oxidized before the phosphorus and transferred to the slag. Slags containing several percent of vanadium were obtained, depending on the vanadium content of the pig iron, whereas normal Thomas slags contain an average of only 0.5 % V.

Oxidation of vanadium-containing pig iron to give vanadium-containing slag was carried out by the Röchling Iron and Steel Works in Völklingen from 1937 using a converter with a very acid lining or a continuously operating oxidizing drum. For details of these abandoned processes see [17].

Processing of Vanadium Slags. The main process used today to produce vanadium oxide from vanadium slags is alkaline roasting. The same process, with minor differences, is also used for processing titanomagnetite ores and vanadium-containing residues.

A vanadium slag has the following approximate composition: 14 % V (=25 % V_2O_5), 1.5 % Ca, 2.5 % Mg, 2.0 % Al, 0.01 % P, 9 % metallic Fe, 32 % total Fe, 7 % Si, 3.5 % Mn, and 3.5 % Ti. The presence of the elements Ca, Mg, and Al, which form water-insoluble vanadates during alkaline roasting, leads to a reduction in yield. Silicon can cause filtration difficulties during leaching of the calcine. Phosphorus, unless removed in a separate treatment, reports practically quan-

titatively to the vanadium oxide, and lowers the vanadium yield in the precipitation process.

The process is shown schematically in Figure 2. The vanadium slag is first ground to $< 100\,\mu m$ (1 – 11 in Fig. 2), and the iron granules contained therein are removed. Alkali metal salts are then added, and the material is roasted with oxidation at 700 – 850 °C in multiple-hearth furnaces or rotary kilns (12 – 20) to form water-soluble sodium vanadate. During roasting, care must be taken to prevent agglomeration of the material by sintering and to ensure rapid cooling after the material leaves the furnace. The roasted product is leached with water (21 in Fig. 2), and ammonium polyvanadate or sparingly soluble ammonium metavanadate is precipitated in crystalline form from the alkaline sodium vanadate solution by adding sulfuric or hydrochloric acid and ammonium salts at elevated temperature (22 – 28). These compounds are converted to high-purity, alkali-free vanadium pentoxide by roasting. The usual commercial "flake" form of vanadium pentoxide is obtained by solidifying the melt on cooled rotating tables (29 – 31 in Fig. 2).

The aluminothermic production of ferrovanadium is shown in Figure 2 (32 – 34), as well as wastewater purification (35 – 44), including the reduction of Cr(VI) to Cr(III) (35) and the crystallization of sodium sulfate (37).

In Russia, a combination of alkaline roasting and sulfuric acid leaching is used. A disadvantage of this process is the manganese content of up to 2 % in the V_2O_5, caused by acid leaching.

Direct Production of Vanadium Oxide from Titanomagnetite Ores and Clays. If the ores contain > 1 % vanadium, they can be directly converted to vanadium pentoxide. The gangue material is first removed from the ore by flotation, and the ore is then mixed with sodium carbonate, pelletized, and roasted in shaft furnaces or rotary kilns at 1000 °C. The sodium metavanadate formed is leached out with water, and vanadium pentoxide is obtained from this by the same method as that used in the roasting process for vanadium slags. The leach residue is used to produce pig iron if its ilmenite content is sufficiently low [15].

4.2. Processing of Other Raw Materials

Hydrometallurgical methods or a combination of pyrometallurgical and hydrometallurgical processes are used to produce vanadium oxides and salts from other raw materials. In the combined processes, thermal treatment is followed by alkaline or, more rarely, acid processing.

Acid Processes. Vanadium-containing oil residues and spent catalysts are digested with sulfuric acid, often under reducing conditions with addition of SO_2. After removal of the impurities, the solution is oxidized, and polyvanadate and calcium or iron vanadate are precipitated by partial neutralization of the acid [13].

Acid digestion was formerly an important method of treating carnotite, a uranium – vanadium ore. After the uranium had been removed from the solution in sulfuric acid by solvent extraction, the vanadium was partially reduced with iron powder and solvent extracted. After re-extraction, the vanadium was in the form of an acid solution of vanadyl sulfate. This was oxidized with sodium chlorate at elevated temperature, and precipitated as red cake, a mixture of sodium and ammonium polyvanadate, by adding ammonia or ammonium salts. This precipitate was roasted to convert it into alkali-containing V_2O_5 [13], [18].

Historically, Pb – Zn – V concentrates from Namibia were subjected to acid treatment process. However, the mining of these ores became uneconomic and was discontinued in 1978.

The ore concentrate produced by flotation was ground and leached with dilute sulfuric acid (10 – 15 %). This led to the formation of insoluble lead sulfate. The solubility of the vanadium was considerably increased by simultaneously passing SO_2 through the liquor. Phosphorus was removed by adding sodium zirconate to precipitate sparingly soluble zirconium phosphate. The filtrate, which contained mainly $ZnSO_4$ and $VOSO_4$, was treated with H_2S to precipitate As and Cu. The pH of the clear solution was increased to 1 – 2 by addition of sodium carbonate, and tetravalent vanadium was oxidized to the pentavalent state by heating with sodium chlorate. More sodium carbonate was added to the iron-containing solution to increase its pH to 4, precipitating a polyvanadate containing iron and sodium. This precipitate was filtered and treated

with a solution of an ammonium salt to replace the sodium ions by ammonium ions. It was then dried and converted to V_2O_5 by fusion.

Zinc carbonate was precipitated from the filtrate after the polyvanadate precipitation.

Combination of Pyrometallurgical and Alkaline Hydrometallurgical Methods. This combined process, which is preferred in practice, is used to treat vanadium-containing residues and spent catalysts. (It was formerly also used for V-containing clays, phosphates, and Pb – Zn vanadates.) The vanadium, which is mainly trivalent, is oxidized at high temperature and converted to alkali metal vanadate, which can be leached with water.

The best known process is alkaline roasting, in one version of which the ore is pelletized with sodium carbonate or compacted. After leaching, the solutions are acidified and ammonium salts are added, precipitating the vanadium as polyvanadate, which is then converted to vanadium pentoxide by calcination.

In the treatment of Pb – Zn vanadates, the zinc and lead were first reduced with carbon in the presence of added sodium carbonate in short drum furnaces. The zinc was distilled off and the lead tapped off as molten metal. The vanadium was then present in the alkaline slag in water-soluble form.

Production of Vanadium Pentoxide from Oil Residues and Boiler Ash. Appreciable amounts of vanadium are present in mineral oil, especially Venezuelan and Russian oils. The vanadium accumulates in the soot and ash of oil-fired boilers and in oil distillation residues and is sold in this form by power stations and refineries. These secondary raw materials, which sometimes contain $> 50\,\%$ V_2O_5, can be blended in the pyrometallurgical/hydrometallurgical process [13] or treated separately.

The extraction of vanadium from mineral oil combustion residues is gaining in importance, since the asphalt-like oil deposits of the Orinoco basin in Venezuela can now be processed into a fuel resembling mineral oil by emulsification with water with addition of magnesium nitrate. The fuel is used for energy generation in power stations. The amount of vanadium in the resulting boiler ashes is expected to reach the same order of magnitude as is currently generated in vanadium slags.

Production of V_2O_5 during the Processing of Bauxites. Some deposits of bauxite contain high levels of vanadium, and during alumina production this ends up in the salt residue, from which V_2O_5 can be obtained. This process is more expensive than vanadium production from slags and causes severe wastewater treatment problems due to the arsenic originating from the raw material [19]. Small amounts of vanadium are obtained by this method in India and Hungary [13].

5. Production of Vanadium, Ferrovanadium, and Other Alloys

5.1. Reduction Behavior of Vanadium Oxides

The most important oxide obtained on treating raw materials is vanadium pentoxide, V_2O_5 (see Chap. 6).

The oxygen partial pressure in equilibrium with the vanadium oxides in accordance with the equations

$$2\,V_2O_5 \rightleftharpoons 2\,V_2O_4 + O_2$$

$$2\,V_2O_4 \rightleftharpoons 2\,V_2O_3 + O_2$$

$$2\,V_2O_3 \rightleftharpoons 4\,VO + O_2$$

$$2\,VO \rightleftharpoons 2\,V + O_2$$

can be calculated from thermodynamic data [20]. The reactions are strongly endothermic, and have positive free enthalpies in the temperature range 298.15 – 2000 K (Fig. 3). V_2O_5 is the only oxide which dissociates to a large extent, the oxygen pressure reaching 0.08 MPa at 2000 K. In the presence of reducing gases such as CO and H_2, the higher oxides are reduced to V_2O_3:

$$V_2O_4 + CO \rightleftharpoons V_2O_3 + CO_2$$

The reduction of V_2O_3 by CO or H_2 in accordance with the equation

$$V_2O_3 + CO \rightleftharpoons 2\,VO + CO_2$$

does not go to completion [20], but reduction by carbon is almost complete:

$$V_2O_3 + C \longrightarrow 2\,VO + CO$$

The reaction of VO with carbon initially gives vanadium carbide:

$$VO + 1.88\,C \rightleftharpoons VC_{0.88} + CO$$

In the further reaction of oxide with carbide,

$$VO + 1.14\,VC_{0.88} \rightleftharpoons 2.14\,V + CO$$

it can be calculated from thermodynamic data [20] that the CO pressure will reach ca. 600 Pa at 2000 K. However, VO and C are soluble in vanadium at high temperature. This does not favor carbothermic reduction to pure vanadium metal even under high vacuum, and it is difficult to obtain a metal with low C and O contents [1].

For the metallothermic reduction of vanadium oxide silicon, aluminum, calcium, and magnesium could be considered as possible reagents, of which calcium and magnesium have an especially strong reduction potential. However, reduction with aluminum is incomplete, the vanadium produced being either oxygen-containing and low in aluminum, or aluminum-containing and low in oxygen [21], which, in addition, leads to loss of vanadium in the slag. In the production of VAl, a low-oxygen, aluminum-containing alloy is refined in a second stage using a vacuum induction furnace and is adjusted

Figure 3. Oxygen potentials of oxides of vanadium and other elements as a function of temperature

to the derived final composition. The refinement of aluminum-free vanadium metal is performed in an electron-beam furnace. The even less complete reduction with silicon is only used in the production of ferrovanadium, as the reaction proceeds better in the presence of iron.

Reduction of the oxides with calcium and magnesium goes almost to completion. As these metals are volatile, it is advantageous to carry out the reaction in closed vessels.

5.2. Production of Vanadium Metal and its Alloys

Reduction of Vanadium Oxide with Carbon. Carbothermic reduction of vanadium oxides is possible (Section 4.1), but the vanadium produced is of high oxygen and carbon content; thus, this method is rarely used in practice. Also, the formation of a low-melting ternary eutectic (96.6 % V, 2.8 % C, 0.6 % O; *mp* 1500 °C) prevents the reaction going to completion [22].

Avoidance of these problems by reducing vanadium oxide with vanadium carbide (carbidothermic production) has been proposed [23], [24]. High-purity vanadium ($\geq$ 99.8 % V)

can be obtained by multiple sintering (two indirect sintering stages, one direct stage, and post-sintering).

Reduction of V_2O_5 with Calcium. A pressure vessel lined with pure magnesium oxide is used in this process. A mixture of high-purity V_2O_5, double-distilled calcium chippings, and some high-purity sulfur as a booster is caused to react by heating [25]. This technique leads to a compact metal regulus (8 – 12 kg, 99.5 – 99.8 % V) which is well separated from the slag. With a calcium excess of up to 70 %, a vanadium yield of 85 – 90 % is obtained. The Vickers hardness (HV 10) of this vanadium metal is 80 – 180, depending on the impurities present (mainly O, N, C, and Si) [1].

Reduction of V_2O_5 or V_2O_3 with Aluminum [26], [27]. The reduction

$$3\,V_2O_5 + 10\,Al \longrightarrow 6\,V + 5\,Al_2O_3$$

is self-sustaining (→ Aluminothermic Processes, Chap. 2.1.), i.e., after initiation it proceeds without additional heating. The metal and slag are melted and separate well from each other. An excess of heat is produced during reduction. For process control, only a fraction of the material is ignited primarily and further material is then charged to the melt. To further decrease the exothermicity, a mixture of V_2O_5 and V_2O_3 is used. In the reduction of V_2O_3 with aluminum, boosters such as $KClO_3$ must be added to increase the reaction heat.

In the process developed by Teledyne Wah Chang Albany [28], a vanadium – aluminum alloy containing 13 – 15 % Al is obtained by the aluminothermic reaction of high-purity V_2O_5 with aluminum powder in a closed vessel. The steel reaction vessel is lined with aluminum oxide at the bottom and in the reaction zone. After evacuation, it is purged several times with helium, and the charge is then electrically ignited with a heated resistance wire. The metal blocks obtained are refined in an electron-beam furnace by remelting several times. The high aluminum content leads to the removal of most of the oxygen by volatilization of aluminum suboxides, but nitrogen and silicon cannot be removed by this method. A purity of 99.93 % V can be achieved.

In a similar process [29], the metal produced in a closed reactor by the aluminothermic method is treated at 1700 °C and 10^{-4} Pa in a resistance-heated vacuum furnace, causing most of the aluminum to volatilize. Further purification by melting in an electron-beam furnace gives 99.93 % pure metal.

Refining. Vanadium – aluminum alloys produced aluminothermically can be refined by molten salt electrolysis (electrorefining) [26]. A metal containing ca. 4.8 % Al, 0.09 % O, and 0.08 % N can be refined by this method to give 99.6 % pure vanadium.

The most effective purification of technically pure vanadium is achieved by the van Arkel process. Vanadium and iodine are heated together in a closed, evacuated tube, forming VI_2 and VI_3. These are then sublimed and decomposed in a second reaction chamber on a tungsten or vanadium wire heated to 800 °C, yielding a 99.95 % pure vanadium. The equipment required is complex and expensive, and the industrial potential is limited.

Production of Semifinished Products (Sheet, Rods, Tubes, Wire). The cast blocks of vanadium metal and alloys have a coarse structure which must first be converted into a fine-grained structure by extruding or forging at 900 – 1200 °C and then annealing. To prevent reaction of the vanadium with atmospheric oxygen and nitrogen, the blocks are encased in an iron or stainless steel cladding by vacuum welding. Owing to the good ductility of vanadium, subsequent metal working by rolling, forging, or drawing can be carried out at 100 – 500 °C. Pure vanadium can normally be formed at room temperature into thin sheets, wires, and tubes.

Vanadium and vanadium alloys can be welded using tungsten electrodes protected by an inert gas (TIG welding). Vanadium can be machined like niobium and tantalum. Excessive heating due to machining at high speeds must be avoided [30], [31].

5.3. Ferrovanadium

According to DIN 17 563 [32], ferrovanadium is "a master alloy with a vanadium content of at least 50 wt % produced by reduction of the corresponding raw materials or their concentrates."

In the United States alloys with lower vanadium contents are also commercially available. The iron – vanadium and vanadium – aluminum master alloys and the commercial grades of vanadium alloys are listed in Table 6.

Table 6. Commercial grades of vanadium master alloys [33], [34]

Ferrovanadium	% V	% C	% Si	% Al
FeV 40	35 – 48	0.5	2.0	0.5
FeV 50	48 – 60	0.5	2.0	0.3
FeV 60	50 – 65	<0.15	<1.5	<2.0
FeV 80	78 – 82	0.15	1.5	<1.5

The Fe – V phase diagram (Fig. 4) shows almost complete mutual solubility of the elements. At compositions approximating to FeV below 1200 °C, a σ-phase exists which forms tetragonal crystals.

Figure 4. Phase diagram Fe – V [35]

5.3.1. Production from Vanadium Oxides

The reduction of vanadium oxides is assisted by the presence of iron, as the activity of the vanadium is reduced, and the solubility of oxygen in vanadium – iron is much lower than in pure vanadium, because of the lower melting point [21]. The vanadium oxides can therefore be reduced with carbon, silicon, and aluminum in the presence of iron, the product being ferrovanadium.

Reduction with Carbon. The high affinity of vanadium for carbon leads to carbide formation, so that carbothermic reduction can only be used when there is no requirement for vanadium with low carbon content. The Union Carbide Corporation has developed a process that gives a V_2C-containing alloy known as Carvan [36], with a C content in the range 10 – 13 % [33].

Reduction with Silicon. Under today's conditions for the processing of V_2O_5, silicothermic reduction is no longer generally profitable, as the process has multiple stages and gives a poor vanadium yield in the form of a low-vanadium ferrovanadium. The vanadium losses in this process are 10 – 25 % [37].

Reduction with Aluminum. The high-vanadium grades of ferrovanadium, FeV 60, FeV 80, and FeV 90, are now usually produced by aluminothermic treatment of V_2O_5. The aluminothermic process can readily be controlled on a large scale. It is especially suitable for the treatment of vanadium pentoxide because it gives a high yield of high-grade ferrovanadium in a single process step.

After ignition, the reaction of V_2O_5 with aluminum is self-sustaining. Some of the mixture of V_2O_5 flakes, aluminum powder or granules, fine steel shot, and an initiating mixture (e.g., BaO_2 + Al powder) is ignited, and further quantities of the mixture are then added. The combustion time for the usual batch size (to produce 0.5 – 1 t metal) is only a few minutes. After cooling for 2 – 3 d, the furnace is dismantled, and the block of metal at the bottom is cleaned and crushed or ground to the commercially desired particle size.

As the reaction proceeds very rapidly, the aluminum in the metal and the vanadium oxide in the slag may not attain equilibrium, so that the vanadium content of the slag may be too high. To prevent this, an electric arc is ignited after completion of the aluminothermic reaction to maintain the molten state of the melt and the slag until reaction is complete [38].

5.3.2. Direct Production from Slags and Residues

Enriched vanadium-containing oxidation slags (see Chap. 4) can also be processed directly to a technical-grade ferrovanadium. In the method

of Christiania Spigerverk [39], a 50 % ferrovanadium is obtained in an electric arc furnace by a two-stage reduction process. In the first stage, the FeO fraction of the slag is reduced with ferrosilicon (FeSi 75) with addition of lime, and in the second stage the slag obtained in the first stage is reduced with 90 % silicon to give a ferrovanadium alloy. The vanadium yield is 80 %, and the FeV still contains traces of Si, Cr, Mn and Ti.

Ferrovanadium can be obtained by the electrosilicothermic treatment of high-vanadium boiler ashes and enriched fly ash, either alone or in combination with vanadium-containing oxidation slags, depending on their composition. As oil residues and fly ash contain only small amounts of iron, the iron removal stage normally necessary with oxidation slags can be omitted.

Figure 5. Phase diagram Al – V [35]

5.4. Production of Other Vanadium Master Alloys

Vanadium – Aluminum Master Alloys. In the production of vanadium-containing titanium alloys, especially TiAl 6 V 4, the vanadium is added as a vanadium – aluminum alloy. The Al – V phase diagram (Fig. 5) shows a higher solubility of aluminum on the vanadium-rich side. This results in a wide range of composition in which vanadium – aluminum alloys can be produced:

VAl 40/60	38 – 42 % V
VAl 50/50	45 – 54 % V
VAl 65/35	60 – 65 % V
VAl 80/20	78 – 82 % V
VAl 85/15	83 – 87 % V

Vanadium – aluminum alloys are produced aluminothermically. The excess heat produced in this self-sustaining reaction is controlled by slow charging of the reaction mixture. The vanadium – aluminum alloys have a lower density than vanadium (6.11 g/cm^3). The melting points of the alloys decrease with increasing aluminum content:

	Density, g/cm^3	Melting range, °C
VAl 80/20 (85 % V)	5.2	1850 – 1870
VAl 40/60 (40 % V)	3.8	1360 – 1520

Because of the small difference between the density of the metal and the slag, poor separation or inclusions of slag in the metal can occur in the aluminothermic process. As titanium alloys are used in highly stressed machinery and equipment, the master alloys used are subject to strict quality control and must be free of oxidic inclusions and impurities, especially heavy metals.

Vanadium – aluminum master alloys can also be produced in water-cooled copper molds, preventing contamination by impurities from slag and refractory oxides in the furnace lining [40]. However, the higher cooling rate can lead to inclusion of process slags.

Nitrogen-Containing Vanadium Master Alloys. As vanadium is a strong nitride former, vanadium-containing alloying agents can be nitrided and used for alloying steels with vanadium and nitrogen (see Chap. 5). Examples of nitrogen-containing alloys are ferrovanadium – nitrogen and manganese – vanadium – nitrogen [41].

Other commercial alloys are listed in the following:

VAlFe	69 % V, 19 % Al, 12 % Fe
VAlSn	43 % V, 43 % Al, 14 % Sn
VCrAl	50 % V, 40 % Cr, 10 % Al
VCo	50 % V, 50 % Co
VNi	65 % V, 35 % Ni
VMoAl	50 – 54 % V, 26 % Mo, 22 % Al

6. Uses

Vanadium is mainly used as an alloying element in the steel industry, other major areas of use are [42], [43]

Steel	ca. 85 %
Nonferrous alloys	ca. 9 %
Chemical industry	ca. 4 %
Others	ca. 2 %

The second largest use area is in nonferrous alloys, mostly vanadium-containing titanium alloys and nickel-based superalloys for the aerospace industry. Additional uses are in vanadium-containing alloys for batteries and in grain refining of aluminum alloys. Vanadium compounds, principally the oxidation catalyst V_2O_5, account for only ca. 3 % of vanadium consumption [12].

Addition to Steel. Vanadium is added to steel mainly as ferrovanadium; technical vanadium carbide and vanadium carbonitride are also used. For the simultaneous addition of vanadium and nitrogen, nitrogen-containing Fe – V alloys are available.

Even small additions of vanadium increase the tensile strength and high-temperature strength of carbon steel [1], [56], and it has a grain refining and dispersion hardening effect in tempering steels.

Addition to Titanium. Alloying with vanadium improves the properties of titanium. The most important alloy is TiAl 6 V 4, which has good strength properties at room temperature and good creep resistance. It is mainly used as a wrought alloy and casting alloy in airframe construction for load-bearing components and fixing devices, and in compressor disks and blades in jet engines. Other areas of increasing importance include power stations, shipbuilding, and reactor technology [13]. Other vanadium-containing titanium alloys with similar strength properties to TiAl6V4 include TiAl3–V2.5, TiV15Cr3Sn3Al3, TiV10Fe2Al3, TiAl6V6Sn2, as well as TiV13Cr11Al3 [44], [45].

In light, corrosion-resistant titanium aluminides (intermetallic γ-TiAl phase) with high-temperature strength, small amounts of vanadium (as well as of chromium and manganese) increase ductility at room temperature, which is an important criterion for usability and workability of this otherwise brittle material [46].

Other Uses. *Alloys for Batteries.* Intermetallic phases of the ZrV_2 type (Laves phases), in which vanadium is substituted partially by, e.g., Ni, Cr, Ti, or Mn, are used as electrode materials in metal hydride/nickel hydroxide batteries [47].

Coating materials containing vanadium and vanadium compounds are used in the electronics and glass industries as well as for wear protection.

Gettering materials based on Zr – V – Mn or Zr – V – Fe alloys are used for gas purification and for improving vacuums. The main component of these alloys, which contain up to 30 % vanadium, is zirconium [48]. Gettering materials are specially adapted to individual applications; thus, with the exception of some products of the company SAES Getters, only a few standard alloys are marketed.

Vanadium Metal and Alloys. The use of vanadium as a principal component of alloys is in its infancy. As vanadium has higher thermal conductivity and strength and lower thermal expansion and density than stainless steel [49], it has been considered for cladding nuclear fuels for sodium-cooled fast breeder reactors, in the form of either pure metal or an alloy. In the United States, in the late 1960s, a large-scale development program on vanadium alloys was undertaken by the Atomic Energy Division at Westinghouse. Wide-ranging cooperative research projects in the Federal Republic of Germany in 1964 – 1971 are reported in [31], [50], [51]. A comprehensive review of these developments can be found in [7].

Of the vanadium alloys investigated, those in which titanium, niobium, chromium, and zirconium are the alloying elements seem the most promising.

The behavior of vanadium and its alloys in contact with lithium and sodium is described in [11], [51]. The effect of irradiation by neutrons on the strength properties of vanadium and its alloys is described in [52].

A further possible application of vanadium is in superconductivity. Vanadium – gallium alloys with composition V_3Ga are well known, but

vanadium – niobium alloys containing 30 % Nb and vanadium – hafnium/zirconium alloys also have good superconducting properties.

7. Vanadium Compounds

A large variety of vanadium compounds are used industrially: halides, oxides, nitrates, carbides, silicides, hydrides, vanadates, and organometallics.

Vanadium Oxides. *Vanadium pentoxide* [*1314-62-1*], V_2O_5, M_r 181.88, *mp* 690 °C, ϱ 3.36 g/cm^3, heat of formation ΔH^{298} −1550.8 kJ/mol, is orange yellow in color and is traded as fused flakes or powder. Reaction with alkali metal hydroxides or ammonium hydroxide gives vanadates. V_2O_5 is prepared by thermal decomposition of ammonium vanadates at 500 – 600 °C in an oxidizing atmosphere (air). It is by far the most important vanadium compound. V_2O_5 is used as an oxidation catalyst in heterogeneous and homogeneous catalytic processes for the production of sulfuric acid from SO_2, phthalic anhydride from naphthalene or *o*-xylene, maleic anhydride from benzene or *n*-butane/butene, adipic acid from cyclohexanol/cyclohexanone, and acrylic acid from propane. Minor amounts are used in the production of oxalic acid from cellulose and of anthraquinone from anthracene.

V_2O_5 is used to lower the melting point of enamel frits for the coating of aluminum substrates. FeV and VAl master alloys are preferably produced from V_2O_5 fused flakes due to the low loss on ignition, low sulfur and dust contents, and high density of the molten oxide compared to powder.

Further uses of V_2O_5 are as a corrosion inhibitor in the CO_2 scrubbing solutions of the Benfield and related processes for the production of hydrogen from hydrocarbons, as cathode in primary and secondary (rechargeable) lithium batteries, as UV absorbent in glass, in YVO_4: Eu^{3+} red phosphors for high-pressure mercury lamps and TV screens, for glazes [53], for yellow (SnO_2/V_2O_5) and blue (ZrO_2/V_2O_5) pigments [13], as colloidal solution for antistatic layers on photographic material [54], and as a starting material for the production of carbides, nitrides, carbonitrides, silicides, halides, vanadates, and vanadium salts.

Vanadium trioxide [*1314-34-7*], V_2O_3, M_r 149.88, *mp* 1977 °C, ϱ 4.99 g/cm^3, heat of formation ΔH^{298} −1218.8 kJ/mol, black powder, is formed by thermal decomposition of ammonium vanadates at 600 – 900 °C in a reducing atmosphere (H_2, CO, CH_4, NH_3). The most important application is as an alternative to V_2O_5 in the production of FeV, VAl master alloys, high-purity vanadium metal, and vanadium carbides and carbonitrides [55].

Vanadium suboxides such as V_2O_4 [*12036-21-4*], M_r 82.94, *mp* 1642 °C, heat of formation ΔH^{298} −1427.37 kJ/mol, dark blue in color, or V_6O_{13} [*11099-11-9*], M_r 513.64, colored bluish black, are of minor industrial importance [56]. They are produced by heating stoichiometric mixtures of vanadium oxides or by reduction of ammonium vanadates or V_2O_5 in atmospheres of controlled reduction potential. Bronzes of V_6O_{13} or V_5O_{11} with Li_2O are used for lithium ion batteries.

Vanadates. The most important product is *ammonium metavanadate* [*7803-55-6*], NH_4VO_3, M_r 116.98, heat of formation ΔH^{298} −1551.0 kJ/mol, a white powder. Thermal decomposition starts at 70 °C. It is sparingly soluble in cold water (ca. 1 %), but readily soluble in mono- and diethanolamine. It is precipitated from neutral alkali metal vanadate solutions by the addition of ammonium chloride or ammonium sulfate. Because of its ready conversion to V_2O_5 at elevated temperatures in oxidizing atmospheres, it is used as a substitute in the production of, e.g., DENOX catalysts and zirconium vanadium oxide yellow ceramic colorants.

Ammonium polyvanadate [*11115-67-6*], $(NH_4)_2V_6O_{16}$, M_r 597.72, is an orange powder, produced by the addition of mineral acids and ammonium salts to alkali metal vanadates at pH 2 – 3 [57]. It is an intermediate product in the production of vanadium pentoxide.

Sodium ammonium vanadate [*39455-80-6*], $2\,(NH_4)_2O \cdot Na_2O \cdot 5\,V_2O_5 \cdot 15\,H_2O$, M_r1345.77, an orange powder, is precipitated from sodium vanadate solutions by the addition of ammonium salts at pH 5 – 6. It is almost exclusively used as a soluble oxidation catalyst for the desulfurization of H_2S-containing gases by the Stretford process.

Sodium metavanadate [*13718-26-8*], $NaVO_3$, M_r 121.93 and *potassium metavanadate* [*13769-43-2*], KVO_3, M_r 138.04, both white powders, are water-soluble compounds. They are added as corrosion inhibitors to CO_2 washing solutions in the production of H_2 from hydrocarbons.

Vanadium Salts. *Vanadyl sulfate* [*27774-13-6*], $VOSO_4 \cdot 5\,H_2O$, M_r 253.08, is produced by the reaction of V_2O_5 and SO_2 in aqueous media, and forms blue, water-soluble crystals. It is used in catalyst production as alternative to V_2O_5. In multivitamin/multimineral pills it is the active component for fast energy supply to the muscles by enhancing glucose metabolism in the blood. It acts as an orally applied insulin mimic.

$VOSO_4$, of blue color, and $V_2(SO_4)_3$, of green color, are the feed solutions for the vanadium redox battery. This battery contains vanadium(V) (yellow) and vanadium(II) (pink) in dilute sulfuric acid as electrodes when charged [58].

Vanadyl oxalate [*14974-48-2*], VOC_2O_4, M_r 154.96, forms blue, water-soluble crystals and is used in catalyst production as alternative to vanadates and vanadium oxides.

Vanadium Halides. Only *vanadium oxytrichloride* [*7727-18-6*], $VOCl_3$, M_r 173.30, *mp* −79.5 °C, *bp* 126.7 °C, ϱ 1.82 g/cm^3, a bright yellow liquid, *vanadium tetrachloride* [*7632-51-1*], VCl_4, M_r 192.75, *bp* 148 °C, a red brown liquid, and *vanadium trichloride* [*7718-98-1*], VCl_3, M_r 157.30, boiling range 300 – 400 °C (disproportionates), a deep purple solid, are of commercial interest. Whereas $VOCl_3$ is stable, VCl_4 slowly decomposes into solid VCl_3 and Cl_2. $VOCl_3$ is produced by the reaction of V_2O_5 and carbon with chlorine gas. For the production of VCl_4, oxygen-free vanadium compounds such as vanadium carbide or vanadium carbonitride are reacted with chlorine gas. The chlorides are used as catalysts in the production of EPDM (ethylene – propene – diene) rubber and polyethylene and are starting materials [59] for the preparation of organic vanadium compounds.

Organic Vanadium Compounds. Representatives of this class are vanadium(IV) and vanadium(III) acetylacetonates, naphthenates, octoates, and alkoxides (iso/*n*-butyl, iso/*n*-propyl), which are soluble in organic solvents. They are used in siccatives, antifouling paints, as catalysts for stereospecific organic synthesis, and in chemical vapor deposition (CVD).

Vanadium Carbides [*12070-10-9*]. The monocarbide, VC, has a theoretical carbon content of 19.08 % and melts at 2830 °C. It has a wide phase range. VC is isomorphous with VO and VN. Pure VC can be prepared by carburizing vanadium hydride powder with carbon in a vacuum [60]. Reaction at 800 °C leads to vanadium carbide in which C : V = 0.72 – 0.87.

Industrial-grade VC is produced by heating V_2O_5 or V_2O_3 with carbon at 1100 °C under a protective atmosphere of hydrogen [61], or by reacting V_2O_3 with carbon in a carbon-tube furnace. The crude carbide formed in the first stage is recarburized at 1700 – 2200 °C under vacuum. The final product contains 18.5 – 19 % total-C and up to 0.5 % free carbon. The VC is not completely free of oxygen because of its isomorphism with VO. VC is added to hard metals in amounts of 0.3 – 0.5 %. It acts as a grain growth limiter [3]. Another carbide, V_2C, with a theoretical carbon content of 10.54 %, also exists. This also has a large range of homogeneity, and decomposes at 1850 °C. It is of no industrial importance as such, but is formed in all carbon-containing vanadium alloys.

Vanadium Nitrides [*24646-85-3*]. Three nitrides exist: VN, V_2N, and V_3N. The mononitride, *mp* 2350 °C, is a grayish-brown powder, isomorphous with VC and VO [62]. Its theoretical composition is 78.45 % V, 21.55 % N, but its range of homogeneity extends from $VN_{1.0}$ to $VN_{0.71}$. It can be obtained by the reaction of vanadium tetrachloride with mixtures of nitrogen and hydrogen gas, using the technique of growth on tungsten wires at 1400 – 1600 °C. Although the preparation of VN from vanadium oxides is difficult because of the isomorphism mentioned above, a product containing 78.3 % V, 21.1 % N, and 0.5 % O can be obtained by reduction with carbon in an atmosphere of nitrogen [61].

As vanadium carbides and nitrides are mutually soluble, vanadium carbonitrides with a wide range of C : N ratios can be prepared at

1100–1400 °C. This is true for both V (C, N) and V_2 (C, N). Two broad three-phase regions extend continuously between the corresponding phases VC – VN and V_2C – V_2N.

Vanadium Silicides [*12039-87-1*]. VSi_2, *mp* 1650 °C, can be prepared by sinter metallurgy. For example, the pure substance can be prepared by exothermic reaction sintering of vanadium and silicon powder [63]. In industry, it is obtained by the reaction of vanadium oxides with SiO_2 and carbon (or with SiC) at 1200 – 1800 °C under vacuum.

Vanadium Hydrides [*13966-93-3*]. In the H – V system [64] the following phases occur: β_1, corresponding to ca. V_2H (low temperature), 33 atom % H; β_2, corresponding to V_2H or VH, 33 – 50 atom % H; δ, corresponding to V_3H_2, 40 atom % H; γ, corresponding to VH_2, 66.7 atom % H.

8. Analysis

The most important analysis is the determination of vanadium in raw materials, especially vanadium-containing slags and the commercial products vanadium oxide and ferrovanadium [65].

To determine vanadium in raw materials, the sample is fused with sodium peroxide and sodium carbonate, the solidified product is leached with water, and the vanadium-containing solution so obtained is acidified with sulfuric acid. The vanadium is completely oxidized with potassium manganate(VII) to the pentavalent state, and the solution is back-titrated with iron(II) sulfate, with diphenylamine as indicator.

In the analysis of vanadium oxide, the sample is dissolved in sulfuric acid, completely reduced with iron(II) sulfate to the tetravalent state, and back-titrated potentiometrically with potassium manganate(VII) solution, using a calomel reference electrode.

Ferrovanadium is also analyzed potentiometrically. The sample is dissolved in sulfuric/nitric acid, and is then oxidized by potassium manganate(VII). The vanadium, now in pentavalent form, is reduced with iron(II) solution, and potentiometrically back-titrated with potassium manganate(VII) solution, using a calomel reference electrode.

9. Economic Aspects

Consumption, Production Capacity, and Prices. The development of vanadium market prices is governed by consumer demand and existing production capacities. For main uses of vanadium and their shares see Chapter 6. The dependence of vanadium production on world steel production is shown in Figure 6 [66]. Total world demand is compared to available production capacities in Figure 7 [67]. This led to the price trend shown in Figure 8 [67].

Figure 6. World production of steel and vanadium

Figure 7. Worldwide vanadium capacity (a) and demand (b)

Figure 8. Vanadium price trends

For the vanadium demand of the western world, South Africa is the major exporter (Table 7). Vanadium in the form of slag and oxides was traded to converters in Europe, Japan, and the United States, for the production of ferrovanadium. Since 1994 most South African suppliers have installed their own ferrovanadium production capacity. This will eventually lead to the nonavailability of South African preproducts for the converters mentioned above. Their plants will have to use other raw materials, such as residues from mineral oil processing, or cease production.

Further suppliers of vanadium oxides are Russia, whose share for export strongly depends on its own economic development; and China, which is expected to turn from an exporter to an importer because of its high economic growth rate.

Ferrovanadium producers are listed in the following [61]:

Country	Company
Argentina	Pamet
	Stein Ferroaleaciones Sacifa
Austria	Treibacher Industrie AG
Belgium	SADACI NV
Brazil	Termoligas Metalurgicas SA
	Cia Paulista de Ferro Ligas
Canada	Masteralloy Products Inc.
	Panzihua Iron and Steel Plant
China	Emei Ferroalloy Plant
	Jinzhou Ferroalloy plant
Czech Republic	Nikom Ferroalloy Plant
Germany	GfE Gesellschaft für Elektrometallurgie
Hungary	Ötvözetgyar; Hungaraloy
India	Birla
Japan	Awamura Metal Industry Co. Ltd.
	Taiyo Mining and Industrial Co.
	NKK Corp.
Mexico	Ferroaleaciones de Mexico
	FERROMEX
	Ferralver SA
CIS	Chusovskoy Metallurgi- cal Kombinat
	Tulachermet Kombinat
Spain	Ferroaleaciones Especiales Asturianas
South Africa	Highveld Steel and Vanadium Corp. Ltd.
	Vametco
	Vantech
United States	BEAR Metallurgical Corp.
	Shieldalloy Corp.
	Strategic Metal Corp., Stratcor

10. Environmental Protection and Toxicology

Soil. In sulfidic and oxidized form, vanadium is a ubiquitous element with an average abundance of 150 mg/kg in the earth's crust. The concentrations vary widely, between a few ppm and 1000 ppm. Depending on geological conditions, even higher values can be found, e.g., 1650 ppm vanadium in oil shales of permic copper schist [68]. The vanadium content of oil shale and mineral oil, in which it is present primarily as porphyrin complexes, is due to biological processes. Higher anthropogenic burdens can be found only in a few isolated geographic locations. In the upper layers of arable soils utilization of mineral fertilizers leads to accumulation of vanadium, which is retained and is only slightly mobile [69].

Air. Vanadium concentrations in uncontaminated air can reach 1 ng/m^3, caused by whirled-up dust from weathered rock and by evaporation of water droplets driven off of surface waters by wind and waves. Increased concentrations are recorded mainly in urban areas. They originate mainly from combustion of coal and especially heavy fuel oil. Concentrations of ca. 10 – 35 ng/m^3 measured in the past (maximum values of up to 1000 ppm, recorded in London, 1962) are lower today, due to the use of efficient waste air purification systems. Industrial activities are of only minor, local importance in the pollution of the air with vanadium.

Water. Vanadium dissolved in water is present almost exclusively in the pentavalent form. In running waters, its concentration range is ca. 0.1 – 220 µg/L [70], the vanadium concentration in the water correlates to these in rocks near the river source in the river bed. The sediment of creeks also mirrors the abundance in the surrounding area. Seawater contains 0.3 – 29 µg/L vanadium [70]. Accumulation does not occur, since the vanadium input from running waters is transferred to the sediment by precipitation and biochemical processes.

Water contamination by vanadium takes place only to a minor extent. For removing vanadium from wastewater, single- or multiple-stage precipitation with iron or lime is employed.

Table 7. World exports of vanadium, 1989 – 1992 [66] (in tonnes of V_2O_5)

Country	Exports				
	1989	1990	1991	1992	%
South Africa [a]	32 950	25 989	25 561	24 000	84.7
New Zealand [b]	2 000	4 000	4 500	3 000	10.6
CIS	1 500	1 350	1 200	1 200	4.2
Others [c]	200	150	150	150	0.5
Total world	36 650	31 489	31 411	28 350	100

[a] Including Republic of South Africa and Bophuthatswana.
[b] Estimates.
[c] China is considered to be a net importer of vanadium at present. Its re-exports are, therefore, not shown in this table.

Table 8. Toxicological data [78], [79]

	Oral LD_{50} (14 d), mg/kg body weight	Inhalative LC_{50} (14 d), mg/L	Dermal LD_{50} (14 d), mg/kg body weight
V_2O_5, analytical grade	470 (male)	11.09 (male)	>2500 (male)

V_2O_3, technical grade	8713 (male)	>6.65 (male)	>2500 (male)
	5639 (female)	>6.65 (female)	>2500 (female)
Ammonium metavandate	218 (male)	2.61 (male)	>2500 (male)
	141 (female)	2.43 (female)	>2500 (female)
Potassium metavanadate	318 (male)	1.85 (male)	>2500 (male)
	314 (female)	4.16 (female)	>2500 (female
$BiVO_4 - BiMoO_4$	>5000	>5.15	

Fauna and Flora. Vanadium is considered to be essential for a number of organisms [71–73]. In vertebrates the average concentration is 0.1 mg vanadium per kg dry matter. Considerably higher concentrations ($\leqq$ 0.1 g/kg) can be found in lower organisms. Especially in one order of invertebrates (ascidians), vanadium accumulates in unusually high amounts [74]. In some species of these organisms, the vanadium is present in green blood cells (vanadocites) and is complexed by pyrrole rings [75]. Data on vanadium concentrations in humans vary widely, between 100 µg [76] and 17 – 43 mg [77]. Fat tissue, bones, teeth, bone marrow, as well as serum are especially rich in vanadium.

In general, the vanadium concentration in plants is related to that in the soil. As with animals, plants vary widely in vanadium content. For example, in fly agaric (*Amanita muscaria*) concentrations 100-times as high as in other fungi are found, independent of location. The reasons for this are not yet known [74].

Toxicology. Toxicity data for some vanadium compounds are given in Table 8. The data show a correlation of toxicity with oxidation state and solubility. Toxicity decreases with decreasing oxidation state and decreasing solubility.

In investigations of neurobehavioral, neuropsychological, psychosomatic, and psychological parameters as a function of exposure to V_2O_5 in dust among workers in an industrial plant, no significant changes compared to uncontaminated persons were found, independent of the concentration of vanadium pentoxide [80].

Occupational Safety. For vanadium pentoxide, there is a total dust limit value (0.5 mg/m^3) and a limit value for fine dust (0.05 mg/m^3); in Germany, the definition of the latter is based on studies on volunteers [81].

Drugs used in veterinary medicine include those originally developed for use in human medicine and later investigated for the treatment of animals. Such drugs are often used to treat horses and companion animals such as dogs and cats but are generally not used to treat foodproducing animals unless drug residues in food and other food safety issues have been investigated. Human drugs used in animals include various antibiotics (e.g., penicillins, cephalosporins, aminoglycosides, and tetracyclines), drugs affecting the cardiovascular system (e.g., digoxin, lidocaine, furosemide), anticonvulsant drugs (e.g., phenobarbital and phenytoin), anesthetics (e.g., halothane, pentobarbital), and analgesics (e.g., morphine, oxycodone, phenylbutazone, and aspirin).

Other drugs have been developed specifically for use in veterinary medicine. Some of these are used to prevent or treat parasitic infections unique to animals. Other veterinary drugs are used to increase weight gain in cattle, sheep, and pigs to decrease production costs and shorten the time until the animal is slaughtered for meat. Other veterinary drugs are close structural analogues of and are used similarly to drugs used in human medicine. For example, the animal tranquilizer acepromazine is a close structural analogue of chlorpromazine and other human tranquilizers.

The following chapters describe some of the veterinary drugs approved for use in the prevention or treatment of various diseases of animals. Human drugs that are not specifically approved by a regulatory agency for use in veterinary medicine are not included.

1. Antibiotics and Antibacterial Drugs

1.1. Sulfonamides (see also → Chemotherapeutics, Chap. 2.7.3.)

Sulfonamides are derivatives of 4-aminobenzenesulfonamide. These substances are weak acids with differing degrees of water solubility.

Sulfonamides are broad-spectrum bacteriostatic drugs, active against a wide range of gram-positive and gram-negative bacteria. Their antibacterial activity is increased by various diaminopyrimidines,in combination with which they are frequently marketed. Sulfaquinoxaline has both antibacterial and coccidiostat activity.

Sulfonamides are believed to act by inhibiting the conversion of *p*-aminobenzoic acid to dihydrofolic acid in sensitive bacteria. The diaminopyrimidines such as trimethoprim and ormetoprim inhibit conversion of dihydrofolic acid to tetrahydrofolic acid. Inhibition of both steps

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_387

by administration of a combination of these two groups of drugs is common and leads to greater antibacterial efficacy than either drug alone. Some combinations are bactericidal to certain organisms.

Sulfonamides

Sulfadiazine

Sulfamethazine

Sulfaquinoxaline

Sulfadimethoxine

Sulfamerazine

Sulfapyridine

Sulfadoxine

Sulfathiazole

Sulfamethazine [*57-68-1*] (sulfadimidine) is used in the treatment of bacterial enteritis and to maintain weight in the presence of atrophic rhinitis in pigs. In combination with chlortetracycline it is used to maintain weight gains in beef cattle suffering from respiratory diseases such as shipping fever. In combination with chlortetracycline and penicillin it is used to promote growth and increase feed efficiency in swine weighing up to 34 kg. Sulfamethazine is frequently found as an illegal residue in meats in the United States.

Sulfaquinoxaline [*59-40-5*] is used to treat or control outbreaks of coccidiosis caused by *Eimeria tenella, E. necatrix, E. acervulina, E. maxima*, or *E. brunetti* in chickens; by *E. meleagrimitis* or *E. adenoeides* in turkeys; and by *E. bovis* or *E. zurnii* in cattle. It is also used to treat or control fowl cholera caused by *Pasteurella multocida*, as well as fowl typhoid caused by sensitive organisms.

Sulfadimethoxine, sulfapyridine, sulfamerazine, sulfadoxine, and sulfadiazine are other sulfonamides used in veterinary medicine to treat infections caused by various bacteria including streptococci, staphylococci, escherichia, salmonella, klebsiella, proteus, or shigella organisms.

1.2. β-Lactam Antibiotics (see also → Antibiotics, Chap. 3.1.)

Penicillins are semisynthetic or synthetic derivatives of 6-aminopenicillanic acid produced by *Penicillium chrysogenum*, whereas cephalosporins are derivatives of 7-aminocephalosporanic acid, originally produced by cultures of *Cephalosporium acremonium.* Modifications of the side chains of both compounds have produced antibiotics with different antimicrobial spectra and pharmacokinetic properties.

β-Lactam antibiotics are bactericidal drugs with gram-positive activity in the older agents and broad-spectrum or gram-negative activity in some newer agents. Organisms producing β-lactamase hydrolyze the β-lactam ring of the penicillins and render them inactive. Clavulanic acid is a β-lactamase inhibitor that is marketed in combination with amoxicillin.

β-Lactam antibiotics inhibit cell wall synthesis in susceptible organisms. They inhibit transpeptidases, which prevents cell wall synthesis and eventually causes lysis of the bacterial cell.

The most commonly used penicillin in veterinary medicine is penicillin G. It is often formulated in combination with procaine or benzathine to produce a poorly soluble salt that dissolves slowly after intramuscular administration. Oral administration of penicillin results in relatively poor bioavailability due to hydrolysis in the acid environment of the stomach.

Semisynthetic penicillins such as ampicillin [*69-53-4*], amoxicillin [*26787-78-0*], hetacillin

[*3511-16-8*], and ticarcillin are used in veterinary medicine to treat infections caused by susceptible organisms. Amoxicillin is a broad-spectrum antibiotic active against many gram-positive and gram-negative organisms, except those producing β-lactamase.

Cephalosporins approved for use in veterinary medicine include cefadroxil and ceftiofur. Cefadroxil [*66592-87-8*] is a first-generation cephalosporin with good activity against gram-positive bacteria and some activity agains gram-negative organisms. Ceftiofur [*80370-57-6*] is active against gram-positive and gram-negative bacteria, including those that produce β-lactamase.

1.3. Tetracyclines (see also → Antibiotics, Chap. 3.2.)

Chlortetracycline and oxytetracycline are produced by *Streptomyces aureofaciens* and *S. rimosus*, respectively. Tetracycline is produced from chlortetracycline, and doxycycline is a semisynthetic derivative. Many of the tetracyclines form chelates with cations such as calcium and magnesium, rendering them inactive. Chlortetracycline has a chlorine atom at C-7 and oxytetracycline bears a hydroxy group at C-5, compared to tetracycline. Doxycycline has a hydroxy group and a hydrogen atom at C-5 and a methyl group at C-6, compared to tetracycline. All are weak bases that form salts with strong acids such as hydrochloric acid.

The tetracyclines are broad-spectrum antibiotics that are bacteriostatic in vitro. Good activity against various rickettsiae such as those responsible for Potomac Horse Fever has been demonstrated. Bacterial resistance often develops after exposure of bacteria to the tetracyclines by plasmid-mediated interference with transport of the drug to the ribosome, increased rate of removal from the ribosome, or decreased effect on the ribosome.

The tetracyclines inhibit bacterial protein synthesis by reversible binding to the 30 S ribosomal subunit of sensitive bacteria.

Tetracycline [*60-54-8*] is marketed in oral formulations including tablets and a soluble powder for dissolution in drinking water and milk. It is used in the treatment of bacterial enteritis caused by *Escherichia coli* and bacterial pneumonia caused by various species of *Pasteurella, Hemophilus*, and *Klebsiella*.

Tetracycline

Oxytetracycline [*79-57-2*] is marketed in a number of formulations including medicated feeds, parenteral products, and ointments. Terramycin Soluble Powder contains oxytetracycline hydrochloride and is used to treat bacterial enteritis in several species, shipping fever complex in cattle, liver abscesses in cattle, atrophic rhinitis in swine, leptospirosis in swine, enterotoxemia in sheep, as well as bluecomb, air-sac infection, sinusitis, fowl cholera, and hexamitiasis in poultry.

Chlortetracycline [*57-62-5*] is marketed in a number of products for veterinary use. As Aureomycin 2G Type C Medicated feed for swine, beef and dairy cattle, sheep, and horses it is used to promote growth and improve feed efficiency and as an aid in the prevention of bacterial swine enteritis. It is also employed in the treatment of bacterial enteritis and in reducing the spread of leptospirosis in swine. It is utilized in cattle to reduce losses due to shipping fever complex and for prevention of anaplasmosis, bacterial diarrhea, and bacterial foot rot. Aureomycin 70 Type A Medicated Article is used in the manufacture of various animal feeds. It is used to treat chronic air-sac infection and bluecomb and to prevent synovitis in chickens.

Doxycycline [*17086-28-1*] is used to treat infections caused by susceptible bacteria; in contrast to the other tetracyclines it is not usually administered as a feed additive.

1.4. Aminoglycosides/Aminocyclitols

(see also → Antibiotics, Chap. 3.3.)

The aminoglycoside antibiotics are produced by species of *Streptomyces* ("mycins") and *Micromonospora* ("micins"). They consist of one or more aminosugars attached to an aminocyclitol ring through a glycosidic bond. The aminocyclitol is either streptidine (streptomycin and dihydrostreptomycin) or 2-deoxystreptamine (all other available aminoglycosides).

Streptomycin: $R_1 = CHO$
Dihydrostreptomycin: $R_1 = CH_2OH$

The aminoglycosides are highly polar drugs due to the large number of hydroxy and amino groups.

The aminoglycoside antibiotics are used primarily to treat infections caused by susceptible gram-negative aerobic bacteria. Bacterial resistance is plasmid mediated and results in bacterial modification of the aminoglycoside; the modified aminoglycosides are not clinically active. Strict anaerobes are resistant to aminoglycosides because they lack the mechanism necessary to transport the drug to the site of action. Due to their high polarity the aminoglycoside and aminocyclitol antibiotics are not well absorbed after oral administration. However, they are sometimes administered orally to reduce bacterial populations in the gastrointestinal tract. The aminoglycoside antibiotics most commonly used in food animal production are gentamicin, neomycin, streptomycin, and dihydrostreptomycin.

The aminoglycosides bind with the 30 S ribosomal subunit of susceptible bacteria and disrupt protein synthesis, resulting in a rapid bactericidal effect.

Aminoglycoside Antibiotics. *Streptomycin* [*57-92-1*] is produced by *Streptomyces griseus*; it is marketed as the sulfate salt in combination with bacitracin methylene disalicylate as Entromycin Powder for the treatment of bacterial enteritis and the associated diarrhea in dogs.

Dihydrostreptomycin [*128-46-1*] is a semisynthetic aminoglycoside produced by the reduction of streptomycin; it is no longer used in human medicine because of ototoxicity. It is marketed in combination with procaine penicillin G in an oil suspension as Quartermaster Suspension for intramammary use to reduce existing infection and to prevent new infection with *Staphylococcus aurea* in dry cows.

Kanamycin [*8063-07-8*] is an antibiotic complex produced by *Streptomyces kanamyceticus* and consists primarily of kanamycin A and two minor components, one of which is designated kanamycin B. Kanamycin is marketed in combination with bismuth subcarbonate and attapulgite as Amforol suspension and tablets for treatment of bacterial enteritis and the associated diarrhea in dogs.

Amikacin [*37517-28-5*] is a semisynthetic aminoglycoside derived from kanamycin A. It frequently has activity against organisms that have developed resistance to other aminoglycosides.

Amikacin

It is marketed as Amiglyde-V as the sulfate salt for injection and intrauterine infusion. The parenteral formulation is indicated for the treatment of skin and soft tissue infections caused by *Pseudomonas* species and *E. coli*, and urinary tract infections caused by *E. coli* and *Proteus* species. The intrauterine infusion is used for the treatment of uterine infections caused by susceptible organisms in the mare.

Gentamicin [*1403-66-3*] is an antibiotic complex produced by *Micromonospora purpurea* and *M. echinospora*; it consists of three substances designated gentamicins C_1, C_{1a}, and C_2.

Gentamicin C_1: R = $CHCH_3NHCH_3$
Gentamicin C_{1a}: R = CH_2NH_2
Gentamicin C_2: R = $CHCH_3NH_2$

It is marketed as the sulfate salt as Garacin oral solution and in injectable form for treatment of colibacillosis in weanling swine caused by strains of *E. coli* sensitive to gentamicin, and swine dysentery associated with *Treponema hyodysenteriae*. Gentamicin is also available as Gentocin solution for parenteral administration to control bacterial infections of the uterus in horses and as an aid in improving conception in mares.

Aminocyclitol Antibiotics. *Spectinomycin* [*1695-77-8*] is an aminocyclitol antibiotic produced by *Streptomyces spectabilis*.

Spectinomycin

It is marketed as an oral solution as Spectam Scour-Halt for the treatment of infectious diarrhea in baby pigs caused by *E. coli*. It is also available as Spectam Injectable for treating airsaculitis and chronic respiratory disease associated with susceptible organisms in turkey poults.

Apramycin [*37321-09-8*] is an aminocyclitol antibiotic that is a component of the nebramycin complex and is produced by a strain of *Streptomyces tenebarius.* Apramycin is marketed as its sulfate salt as Apralan 75 Premix/Medicated, a type A medicated article for oral use in pigs, and Apralan Soluble Powder. Both products are used for the control of porcine colibacillosis caused by susceptible strains of *E. coli*.

1.5. Macrolide Antibiotics

Macrolide antibiotics (see also → Antibiotics, Chap. 3.5.,) all possess a macrocyclic lactone ring attached to one or more amino sugars. The macrolide ring may contain 12, 14, 16, or 17 atoms.

Macrolide antibiotics have good antibacterial activity against many gram-positive organisms such as *Mycoplasma* and *Chlamydia* but have little or no activity against most gram-negative bacteria.

The macrolide antibiotics inhibit protein synthesis by binding to the 50 S ribosomal subunits of sensitive microorganisms. Gram-positive microorganisms accumulate much more macrolide antibiotic than do gram-negative microorganisms. Since bacterial cell walls are much more permeable to the unionized form, these drugs generally exhibit greater antimicrobial activity under alkaline conditions.

Erythromycin [*114-07-8*] is a mixture of three components, designated Erythromycin A, Erythromycin B, and Erythromycin C, produced by *Streptomyces erythreus*. Erythromycin A is the major component. All are macrolide antibiotics consisting of a fourteen-membered lactone ring attached to desosamine, an amino sugar, and cladinose or mycarose. Erythromycin, isolated in 1952, was the first macrolide antibiotic widely used in medicine. It is active against a wide variety of gram-positive bacteria and mycoplasmas and is widely used in veterinary medicine. Erythromycin is degraded by stomach acids and is therefore marketed as various esters (e.g., stearate and ethylsuccinate) or enteric coated products for oral administration. Erythromycin has a relatively large distribution volume and is extensively distributed to various tissues, particularly the lungs, kidneys, and liver, where it may attain tissue concentrations higher than the corresponding plasma concentration.

Erythro-100 and Erythro-200 Injectable are erythromycin preparations in sterile solution containing 100 and 200 mg/L of erythromycin for intramuscular administration. In sheep it is indicated for the prevention of lamb dysentery and in the treatment of upper respiratory infections. In pigs it is used for treating respiratory syndrome and as an aid in the management of

mastitis, metritis, and leptospirosis in sows at farrowing time and scours in young pigs. It is indicated in cattle for the treatment of pneumonia, shipping fever, mastitis, metritis, foot rot, and as an aid in reducing weight loss during shipping.

	R_1	R_2
Erythromycin A	OH	CH_3
Erythromycin B	H	CH_3
Erythromycin C	OH	H

Gallamycin-Dry Cow and Gallimycin-36 are tubes containing erythromycin for administration into the udders of nonlactating and lactating cows, respectively, for the treatment of acute and chronic mastitis caused by *Staphylococcus aureus, Streptococcus agalactiae, S. dysgalactiae,* and *S. uberis*. Uddermate is indicated for mastitis treatment in lactating cows only.

Oleandomycin [*3922-90-5*] consists of a single component produced by *Streptomyces antibioticus*. It is a macrolide antibiotic consisting of a fourteen-membered lactone ring attached to desosamine and another sugar moiety. Oleandomycin has an antibacterial spectrum similar to that of erythromycin but is less potent. It is marketed as its phosphate salt and as its triacetyl derivative, troleandomycin.

Tylosin [*1401-69-0*] is a macrolide antibiotic containing a sixteen-membered lactone ring substituted with various sugar moieties. Tylosin is a mixture of four related compounds, designated tylosin A, B, C, and D, with tylosin A the major component.

Tylosin is used as a feed additive for growth promotion and as an antibacterial drug in veterinary medicine. It is one of the most effective macrolide antibiotics against *Mycoplasma*. Tylosin was isolated from a strain of *Streptomyces fradiae* found in soil from Thailand.

Tylosin

Tylan 40 is a feed additive and antibiotic containing 40 g of tylosin as tylosin phosphate per pound. Tylan 40 is used in swine to maintain weight gain and feed efficiency in the presence of atrophic rhinitis. It is also used in swine to increase the rate of weight gain and to improve feed efficiency; it is employed to prevent, treat, and control swine dysentery. It is used to reduce the incidence of liver abscesses caused by *Spherophorus necrophorus* and *Corynebacterium pyogenes* in beef cattle. It is utilized in chickens to improve feed efficiency and to control chronic respiratory disease caused by *Mycoplasma gallisepticum.*

Tylosin Injection and Tylan Injection are formulated with 50 and 200 mg of the base per milliliter. The solution is administered intramuscularly to beef cattle and nonlactating dairy cattle to treat bovine respiratory complex associated with *Pasteurella multocida* and *Corynebacterium pyogenes*, foot rot and calf diphtheria caused by *Fusobacterium necrophorum*, and metritis caused by *Corynebacterium pyogenes.* Tylosin Injection is administered intramuscularly to swine to treat swine arthritis caused by *Mycoplasma hyosynoviae,* swine pneumonia caused by *Pasteurella* spp, swine erysipelas caused by *Erysipelothrix rhusiopathiae*, and acute swine dysentery associated with *Treponema hyodysenteriae*.

Spiramycin [*8025-81-8*] is a mixture of three macrolide antibiotics containing a sixteen-membered lactone ring, substituted with amino sugars and mycarosyl. The components are designated spiramycin I, II, and III, with spiramycin I being the most important. The antimicrobial spectrum of spiramycin is similar to that of other macrolide antibiotics, but its activity

against *Treponema* is greater than that of erythromycin or oleandomycin.

1.6. Amphenicols

Chloramphenicol is produced by *Streptomyces venezuelae*; it is unique among natural compounds in having a nitrobenzene moiety and a dichloracetamide group. The active form of chloramphenicol has the *threo* configuration. Chloramphenicol is not ionizable at physiologic pH values and is relatively lipophilic. Thiamphenicol differs from chloramphenicol in that it has a methylsulfonyl group in place of the nitro group. Florfenicol differs from thiamphenicol by having a fluorine atom substitued for the hydroxy group at C-3. Thiamphenicol and florfenicol are totally synthetic.

The amphenicols are broad-spectrum antibiotics that are primarily bacteriostatic but may be bacteriocidal to certain bacteria. Gram-negative bacteria generally acquire resistance to chloramphenicol and thiamphenicol through plasmid-mediated transfer of acetyl transferase, which inactivates these drugs.

Florfenicol, lacking the hydroxy group that is acetylated in these other drugs, is not affected by the presence of acetyl transferases and therefore is effective against many chloramphenicol-resistant organisms.

Amphenicol antibiotics bind to the 50 S ribosomal subunits of susceptible bacteria, thereby inhibiting protein synthesis.

Chloramphenicol

3-Acetylchloramphenicol

Chloramphenicol [*56-75-7*] is a broad-spectrum antibiotic marketed as Bemacol ointment and Chlorbiotic ointment for topical treatment of bacterial conjunctivitis due to susceptible organisms in dogs and cats. It is also available as chloramphenicol tablets and capsules for treatment of bacterial infections in dogs. Chloramphenicol palmitate is an oral suspension for treatment of bacterial infections in dogs.

Chloramphenicol use in food-producing animals is not allowed due to the possibility of food contamination.

Thiamphenicol [*15318-45-3*] is a broad-spectrum antibiotic used in veterinary medicine. The D-form is used as an antimicrobial drug, and the DL-form in the control of fowl cholera.

Thiamphenicol

Florfenicol [*73231-24-2*] is a broad-spectrum antibiotic used to treat bovine respiratory disease complex. It is also effective in the treatment of various fish diseases such as furunculosis in Atlantic salmon, pseudotuberculosis in yellowtail, and vibriosis in goldfish.

Florfenicol

1.7. Tiamulin

Tiamulin [*55297-95-5*] is a diterpene antibiotic containing an eight-membered carbocyclic ring. It is a derivative of pleuromutilin, an antibiotic substance produced by *Pleurotus mutilis* and *P. passeckerianus*.

Tiamulin is effective against gram-positive bacteria, *Mycoplasma*, and *Serpulina hyodysenteriae*. Tiamulin interferes with the metabolism and elimination of polyether ionophores (e.g., monensin, salinomycin, lasalocid, and narasin). This interaction is a potential cause of toxicity

when used in combination with these antibiotics. For this reason the combination of tiamulin and ionophore antibiotics is generally contraindicated.

Tiamulin

Denagard soluble antibiotic is a fine, white granular powder containing 45 wt % tiamulin designed for administration in the drinking water of swine to treat infections caused by *Treponema hyodysenteriae* and *Hemophilus pleuropneumonia*. Denagard 10 is a feed additive and antibiotic containing 10 g of tiamulin as the hydrogenfumarate salt per pound. This product is used to treat swine dysentery associated with *Treponema hyodysenteriae* and as a feed additive to increase weight gain. Swine being treated with Denagard 10 should not have access to feeds containing ionophore antibiotics.

1.8. Peptide Antibiotics

The peptide antibiotics (see also → Antibiotics, Chap. 3.7.) are a diverse group of compounds having peptides arranged in linear or ring structures. Many polypeptide antibiotics have been used in veterinary medicine as feed additives and drugs. Bacitracin, enramycin, and virginiamycin are widely used for growth promotion, improvement of feed efficiency, and treatment of disease.

The various polypeptide antibiotics have different antibacterial spectra and produce their antibacterial effects by a variety of mechanisms.

Actaplanins are a complex of antibiotics produced by *Actinoplanes missouriensis*. Six components designated A, B_1, B_2, B_3, C_1, and G have been isolated and characterized. The drugs have a central peptide core, with the amino sugar ristosamine and up to four neutral sugars attached. The actaplanins are used to promote growth and increase milk production in ruminants.

Avoparcin [*37332-99-3*] is a glycopeptide antibiotic complex produced by *Streptomyces candidus*. It consists of a mixture of α- and β-avoparacin (chlorine-substituted analogue) and is used as an antibacterial agent and growth enhancer.

Bacitracin [*1405-87-4*] is a polypeptide complex produced by *Bacillus subtilis* and *licheniformis*. The commercial product is a mixture of at least nine bacitracins. It is used as local antibiotic, growth promoter, and for enteric infections.

Virginiamycin is an antibiotic complex produced by a *Streptomyces* related to *S. virginiae*. It is a mixture of two principal components designated virginiamycin M_1 [*21411-53-0*] and virginiamycin S_1 [*23152-29-6*]. Virginiamycin is used as an antibiotic and as a feed additive.

Bambermycin [*11015-37-5*] is an antibiotic complex consisting of at least four components: moenomycins A, B_1, B_2, and C with moenomycin A the major component. It is obtained from cultures of *Streptomyces bambergiensis* and others. Bambermycin is used as an antibacterial agent and as a growth promoter in poultry, swine, and calves.

1.9. Ionophore Antibiotics

The ionophore antibiotics are classified as polyethers and contain an acidic functional group at one end of the molecule. The acid group forms a hydrogen bond with a hydroxyl group at the other end of the molecule, giving an inclusion complex with alkyl groups on the outer surface and polar groups on the inner surface. Cations bind to the polar groups on the inner surface.

Ionophore antibiotics were initially developed as poultry coccidiostats but are now also used to promote growth of cattle. They enhance propionic acid production in ruminants by altering rumen fermentation. They are usually added at a rate of 5 – 30 ppm of finished ration to improve feed efficiency of feedlot cattle.

Ionophore antibiotics facilitate transport of monovalent and divalent cations across biological membranes. They selectively transport

sodium and potassium ions between extracellular and intracellular spaces and interfere with potassium ion transport across mitochondrial membranes.

Monensin [*17090-79-8*] is a major component of the antibiotic complex isolated from *Streptomyces cinnamonensis*. It has antibacterial, antifungal, and antiprotozoal activity and is a coccidiostat in chickens. Coban 45 and Coban 60 are feed additives and coccidiostats containing 45 and 60 g of monensin sodium salt per pound for use in poultry; Rumensin 60 is a feed efficiency enhancer for feedlot and pasture cattle containing 60 g of monensin sodium salt per pound. (See picture next page.)

Narasin [*55134-13-9*] is the main component of the polyether antibiotic complex produced by *Streptomyces aureofaciens*. It is used as a coccidiostat and as a growth stimulant. Monteban 45 is marketed as a feed additive and coccidiostat at a concentration of 45 g per pound. Maxiban 72 is a feed additive and coccidiostat containing both narasin and nicarbazine at a concentration of 36 g per pound for use in broiler chickens. (See picture next page.)

Maduramicin [*84878-61-5*] is a polyether antibiotic isolated from a species of *Nocardia*. It is used as a feed additive and coccidiostat. Cygro Type A Medicated Article is a feed additive and coccidiostat containing 4.54 g of maduramicin ammonium salt per pound for prevention of coccidiosis in broiler chickens caused by various species of *Eimeria*.

Lasalocid [*25999-31-9*] was originally isolated from an unknown species of *Streptomyces* from Hyde Park, Massachusetts. It is used as a feed additive and coccidiostat in chickens. Avatec is a medicated premix containing 20 % of sodium lasalocid in a carrier suitable for use in feed for broiler chickens for prevention of coccidiosis. Bovatex is a medicated premix that contains 15 % of sodium lasalocid in a carrier suitable for incorporation in feed to improve feed efficiency and increased rate of gain when used for cattle fed in confinement for slaughter. (See picture next page.)

2. Antimycotics (see also → Antimycotics)

Miconazole and clotrimazole are substituted imidazoles containing one or more aromatic rings with chlorine substituents.

Miconazole [*22916-47-8*] is marketed as its nitrate salt in a number of topical products (e.g., Conofite Cream, Lotion, and Spray and Dermazole Shampoo) for the control of fungal infections caused by *Microsporum canis, M. gypseum*, and *Trichophyton mentagrophytes* in dogs and cats.

Miconazole

Clotrimazole [*23593-75-1*] is marketed as Veltrim Dermatologic Cream for treatment of fungal infections caused by *Microsporum canis* and *Trichophyton mentagrophytes* in dogs and cats.

Clotrimazole

3. Coccidiostats

Coccidiostats are a diverse group of drugs, including the ionophore antibiotics and other substances useful in the control or treatment of coccidiosis.

Coccidiostats affect various stages of the life cycle of species of *Eimeria* that infect the digestive tracts of birds, causing economic losses in commercial poultry operations. Resistance to coccidiostats may develope upon repeated use. Therefore, it has become common practice in the broiler industry to use two or more coccidiostats sequentially at various intervals.

Monensin

Narasin

Lasalocid

Clopidol [*2971-90-6*] is mainly coccidiostatic and is active only against the sporozoite stage of *Eimeria*. It is effective only if administered on the day of exposure to the coccidial oocysts. Clopidol is marketed as a feed additive and is fed at a rate of ca. 125 ppm in the feed.

Amprolium [*121-25-5*] interferes with thiamine utilization in the parasite.

Amprolium is rarely used alone because it has relatively weak activity against *Eimeria maxima, E. mivati*, and other species. It is the only coccidiostat without a withdrawal time in the poultry industry. Amprolium is marketed as Aprol, Amprovine, and Corid in various soluble powders and oral solutions for treatment of coccidiosis in growing chickens, turkeys, and laying hens.

Decoquinate [*18507-89-6*] is a 4-hydroxyquinolone derivative that prevents development of the sporozoite stage by disruption of electron transport in the mitochondrial cytochrome system of the coccidia. Decoquinate is marketed as Deccox as a top dressing for addition to the feed for prevention of coccidiosis caused by *Eimeria bovis* and *Eimeria zurnii* in ruminating calves and cattle.

4. Parasiticides

4.1. Avermectin Derivatives

The avermectins are natural and semisynthetic derivatives of pentacyclic 16-membered lactones related to the milbemycins. The natural compounds are produced by *Streptomyces avermitilis*.

The avermectin antibiotics are very effective and highly potent anthelmintics that are effective by a number of administration routes. They are effective against a wide variety of nematodes as well as external parasites such as lice, flies, and bots. Ivermectin is also effective against the microfilarial and infective stages of canine heartworm disease caused by *Dirofilaria immitis*. Concerns have been expressed about their effects on the environment since they are excreted

in the feces and may affect insects and other organisms responsible for the normal degradation of dung.

These drugs apparently inhibit motility of parasites by increasing the release of γ-aminobutyric acid (GABA) thereby inhibiting neurotransmission. Worms are thereby paralyzed and are expelled from the animal.

Ivermectin [*70288-86-7*], 22,23-dihydroabamectin, is a semisynthetic derivative of abamectin. Ivermectin contains at least 80 % of 22,23-dihydroabamectin B_{1a} and not more than 20 % of 22,23-dihydroabamectin B_{1b}. Ivermectin is marketed as Eqvalan liquid and paste for use in horses for the treatment and control of large

Ivermectin

Component B_{1a}: R = CH_2CH_3
Component B_{1b}: R = CH_3

strongyles, small strongyles, hairworms, pinworms, ascarids, intestinal thread-worms, large-mouth stomach worms, bots, lungworms, summer sores, and cutaneous onchocerciasis. Ivermectin is also available as Heartgard-30 tablets to prevent canine heartworm disease by eliminating the tissue stage of heartworm larvae for a month after infection, and for the treatment and control of ascarids (*Toxacara canis* and *Toxascaris leonina*) and hookworms (*Ancylostoma caninum* and *Uncinario stenocephala*). Ivomec is a 1 % ivermectin solution for treatment and control of internal and external cattle parasites and for treatment and control of gastrointestinal roundworms, lungworms, lice, and mange mites in swine. Ivomec sheep drench is a 0.08 % solution of ivermectin for treatment of gastrointestinal roundworms, lungworms, and nasal bots in sheep.

Abamectin [*71751-41-2*], avermectin B_1, is produced by *Streptomyces avermitilis* and is structurally related to ivermectin. It is a mixture containing at least 80 % of avermectin B_{1a} and not more than 20 % of avermectin B_{1b}. Abamectin is marketed as Affirm, Avomec, and Vertimec for use as an anthelmintic drug.

4.2. Benzimidazole Derivatives

Benzimidazole anthelmintics are widely used in cattle, swine, and horses for controlling various gastrointestinal roundworms, tapeworms, liver flukes, and lungworms. They have a wide range of antiparasitic activity, a high degree of efficacy, and a good safety margin. Most are effective when administered orally. Thiabendazole is also used as a fungicide on many crops.

These drugs inhibit microtubules, inhibit glycogen uptake, and inhibit fumarate reductase in susceptible organisms.

Thiabendazole [*148-79-8*] was one of the first benzimidazole anthelmintic drugs approved for use in animals. It is marketed as Equizole A as a liquid horse wormer in combination with piperazine, and as Equizole suspension for control of gastrointestinal roundworms in cattle, horses, sheep, and goats. It is commercially available as TBZ 6 suspension for treatment and control of roundworm infection in cattle, and as Tresaderm in combination with dexamethasone and neomycin sulfate in solution for treatment of various bacterial, mycotic, and dermatoses and otitis externa in dogs and cats.

Thiabendazole

Other benzimidazole anthelmintics used in veterinary medicine include albendazole, fenbendazole, cambendazole, oxfendazole, oxibendazole, and mebendazole.

4.3. Imidazothiazole Derivatives

Imidazothiazole drugs are broad-spectrum anthelmintics used to treat and control a number of internal parasites affecting several animal species. They can be administered by various routes and are highly efficacious.

Butamisole [*54400-59-8*] is used to treat whipworm and hookworm infections in dogs. It is administered subcutaneously. It is marketed as Styquin, an aqueous solution of the hydrochloride. The product is not to be administered to heartworm-positive dogs or those treated with bunamidine because fatalities have been reported following its use in these animals.

Levamisole [*16595-80-5*] is an anthelmintic that causes paralysis of nematodes by ganglionic stimulation. It is available in several formulations including parenteral solutions, drenches, boluses, and oral gels. Tramisol injectable solution is a 13.65 % solution of levamisole hydrochloride for subcutaneous injection in cattle, and Tramisol Type A Medicated Article is a premix for addition to the feed of cattle and swine.

Levamisole

5. Anti-inflammatory Drugs (see also → Anti-inflammatory – Antirheumatic Drugs)

5.1. Nonsteroidal Anti-inflammatory Drugs

The nonsteroidal anti-inflammatory drugs are lipophilic acids of various structures. Ketoprofen and carprofen are members of the propionic acid class, which also includes ibuprofen, naproxen, and fenoprofen. Meclofenamic acid is a member of the fenamate class of nonsteroidal anti-inflammatory drugs.

The nonsteroidal anti-inflammatory drugs produce anti-inflammatory, antipyretic, and analgesic effects in animals.

They are believed to exert their pharmacologic effects at least in part by inhibiting cyclooxygenase activity, thereby reducing concentrations of prostaglandins, thromboxanes, and prostacyclins. They may also act centrally to reduce pain.

Flunixin [*38677-85-9*] is a nonsteroidal anti-inflammatory drug approved for use in horses. It is marketed as Banamine granules containing flunixin as its meglumine salt, equivalent to 250 or 500 mg of flunixin per 10 or 20 g packet for oral administration, for alleviation of pain and inflammation associated with musculoskeletal disorders of horses. Banamine paste contains 1500 mg of flunixin as its meglumine salt per 30 g syringe for oral administration to alleviate pain and inflammation associated with musculoskeletal disorders of horses. Banamine solution contains 50 mg of flunixin as its meglumine salt per milliliter for alleviation of pain and inflammation associated with musculoskeletal disorders and pain associated with colic in horses. Banamine solution may be administered intravenously or intramuscularly.

Flunixin

Meclofenamic acid [*644-62-2*] is marketed as Arquel granules containing 500 mg of meclofenamic acid per packet for oral administration to horses to alleviate pain and inflammation associated with musculoskeletal disorders.

Meclofenamic Acid

Ketoprofen [*22071-15-4*] is a relatively new nonsteroidal anti-inflammatory drug. It is marketed as Ketofen solution containing 100 mg/mL

of ketoprofen for intravenous administration to horses for alleviating pain and inflammation associated with musculoskeletal disorders.

Ketoprofen

Phenylbutazone [*50-33-9*] is the oldest of the nonsteroidal anti-inflammatory drugs used in veterinary medicine. It is marketed in a number of parenteral and oral formulations. Phenylbutazone tablets containing 100 mg and 1000 mg of active ingredient are available for oral administration to dogs and horses, respectively, for treatment of inflammation associated with the musculoskeletal system. Phenylbutazone solution for intravenous injection contains 200 mg/mL of active ingredient and is indicated for the relief of inflammation associated with the musculoskeletal system of the horse.

Phenylbutazone

Carprofen is the newest member of this group and is used to treat musculoskeletal injuries in horses.

5.2. Steroidal Anti-inflammatory Drugs

The steroidal anti-inflammatory drugs are fluorinated analogues of cortisol. Fluorine substitution has been shown to increase potency.

They are used locally or systemically to produce an anti-inflammatory effect. They have greater anti-inflammatory activity and less sodium-retaining activity than naturally occurring corticosteroids such as cortisol and cortisone.

The steroidal anti-inflammatory drugs inhibit release of arachidonic acid from cell membranes. They thereby interfere with the first step of the arachidonic acid cascade and prevent or reduce the biosynthesis of prostaglandins, prostacyclins, thromboxanes, and other cytokines involved in the inflammatory response.

Betamethasone [*378-44-9*] is marketed as Betasone, a mixture of betamethasone dipropionate and betamethasone sodium phosphate. The betamethasone dipropionate is in aqueous suspension and the betamethasone sodium phosphate is in solution in this product to provide immediate and sustained anti-inflammatory effects in the dog for relief of pruritis associated with dermatoses. Betamethasone is also available as its valerate ester in combination with gentamicin in a spray (Gentocin) and an ointment (Topagen) for topical use to treat superficial lesions caused by bacteria susceptible to gentamicin in the dog.

Betamethasone

Dexamethasone [*50-02-2*] is marketed as Azium powder for cattle and horses and as Azium solution for intramuscular and intravenous administration for treating primary bovine ketosis, and as an anti-inflammatory agent in cattle, horses, dogs, and cats. Dexamethasone is also marketed in combination with the diuretic trichlormethiazide as Naquasone for the treatment of physiological parturient udder edema in cattle.

Dexamethasone

Flumethasosone [*2135-17-3*] is marketed in combination with neomycin sulfate and polymyxin B sulfate in Anaprime Ophthalmic Solution for the treatment of inflammation, edema, and secondary bacterial infections of the eye in dogs. It is also marketed as Flucort solution for intravenous, intramuscular, or subcutaneous administration to horses, dogs, and cats, and intra-articular administration to horses. Flucort tablets are available for oral therapy with flumethasone.

Flumethasone

Isoflupredone [*338-95-4*] is marketed as its acetate ester in combination with neomycin sulfate in Neo-Predef ointment for use in cattle, horses, dogs, and cats, and in combination with both neomycin sulfate and the local anesthetic tetracaine as Neo-Predef, as Tetracaine topical powder, and Tritop topical ointment for use in dogs, cats, and horses. Predef 2 X is a suspension of isoflupredone acetate for intramuscular or intra-synovial use in cattle, horses, and pigs.

Isoflupredone

Triamcinolone [*124-94-7*] is marketed as its acetonide [*76-25-5*] in Vetalog cream, oral powder, tablets, and parenteral solution.

Triamcinolone

Triamcinolone acetonide

6. Respiratory Stimulants

Doxapram [*309-29-5*] is used as a respiratory stimulant during recovery from barbiturate or inhalation anesthesia in dogs, cats, and horses. It produces respiratory stimulation at doses considerably less than those producing CNS stimulation.

Doxapram stimulates chemoreceptors of the carotid and aortic regions and may stimulate the medullary respiratory center.

Doxapram is marketed as Dopram-V injectable for intravenous use in dogs, cats, and horses.

Doxapram

Amiphenazole [*490-55-1*] is a phenyl-substituted thiazolediamine that forms soluble salts with acids.

It is used as a barbiturate and morphine antagonist in animals, and is marketed as Daptizole and Fenamizol.

Amiphenazole

7. Anesthetics

Dissociative anesthetics are rapid-acting, nonnarcotic, nonbarbiturate drugs used to produce anesthesia in cats and dogs (tiletamine only) as well as restraint in nonhuman primates (ketamine only). These drugs produce profound analgesia, normal pharyngeal-laryngeal reflexes, as well as mild cardiac stimulation and respiratory depression.

Ketamine

Tiletamine

Ketamine [*6740-88-1*] is marketed as Ketaset and Vetalar solutions for intramuscular administration to cats and subhuman primates.

Tiletamine is marketed as its hydrochloride salt in combination with zolazepam hydrochloride as Telazol solution for intramuscular administration to dogs and cats.

Zolazepam

α_2-Agonists. The α_2-agonists used in veterinary medicine consist of a substituted aromatic ring attached to a heterocyclic ring containing at least one nitrogen atom. Addition of a methyl group to detomidine produced medetomidine and created an asymmetric center.

The α_2-agonists are sedative and analgesic drugs used to facilitate minor surgical procedures.

Detomidine

Medetomidine

Xylazine

Romifidine

The α_2-adrenoreceptor agonist drugs produce sedation and analgesia via CNS depression. The action of the α_2-adrenoreceptor agonist drugs can be reversed by administration of α_2-adrenoreceptor antagonists such as yohimbine and atipamezole.

Xylazine [*7361-61-7*] is marketed as its hydrochloride salt as Rompun (100 mg/mL) and Anased (20 mg/mL) injectable solutions for intravenous administration to horses and dogs, respectively. The actions of xylazine may be reversed by the administration of yohimbine, an indolalkylamine alkaloid, that blocks those α_2-adrenoreceptors that are stimulated by xylazine.

Detomidine [*76631-46-4*] is marketed as its hydrochloride salt as Dormosedan solution for intramuscular or intravenous administration to horses.

Medetomidine [*86347-14-0*] is marketed as its hydrochloride salt as Domitor, and its dextrorotatory isomer, *dexmedetomidine*, are used to produce sedation and analgesia in many mammalian species but used mainly in the dog and domestic cat.

Romifidine is marketed as its hydrochloride salt.

Reversing Agents. *Yohimbine* [*146-48-5*] is an alkaloid found in *Corynanthe johimbe* and related trees as well as in *Raulwolfia serpentina*. It is marketed as its hydrochloride salt as Yobine to reverse the effects of the α_2-adrenoreceptor agonists.

Yohimbine

Atipamezole

Atipamezole is a synthetic compound marketed as Antisedan to reverse the effects of the α_2-adrenoreceptor agonists.

8. Narcotic Agonists and Antagonists

Narcotic analgesic drugs used in veterinary medicine are synthetic or semisynthetic derivatives of morphine (and related alkaloids) and derivatives of fentanyl.

Narcotic analgesics are used in veterinary medicine to produce tranquilization to assist in the capture of wild and zoo animals, as preanesthetic medications, and as analgesic drugs.

They are believed to exert their effects by acting as agonists at specific opiate receptors located in the brain and possibly other sites in the body. Stimulation of these receptors produces profound analgesia in animals. The actions of the narcotic analgesic drugs may be reversed by the administration of competitive antagonists such as diprenorphine and naloxone.

Numerous narcotic analgesic drugs such as morphine, codeine, oxymorphone (Numorphan), pentazocine (Talwin-V), and butorphanol (Torbugesic and Torbitrol) are used in veterinary medicine. Other narcotics with somewhat specialized application in veterinary medicine are discussed below.

Etorphine/diprenorphine is an agonist/antagonist combination used to produce tranquilization and reversal in large animals. Etorphine [*14521-96-1*] is marketed as its hydrochloride salt as M-99 for intramuscular administration. It is approximately 10 000 times more potent than morphine as an analgesic. It is usually dosed heavily to produce tranquilization and avoid hyperexcitability in wild animals, and then reversed with diprenorphine [*14357-78-9*] (M-5050). Etorphine is also marketed in combination with acepromazine, a phenothiazine tranquilizer, to produce neuroleptic analgesia.

Fentanyl [*437-38-7*] is marketed as its citrate salt in combination with droperidol, a butryphenone tranquilizer, as Innovar-Vet for intravenous or intramuscular use in the dog for various surgical procedures requiring analgesia and tranquilization.

Etorphine

Diprenorphine

Fentanyl

Carfentanil is marketed as its citrate salt as Wildnil for immobilization of free-ranging or confined deer, elk, and moose. Carfentanil is ca. 10 000 times as potent as morphine. The effect of carfentanil is rapidly reversed by the administration of diprenorphine.

Carfentanil

9. Antihistamines (see also → Antiallergic Agents, Chap. 2.)

The antihistamines used in veterinary medicine are classified as ethylenediamine derivatives (i.e., pyrilamine and tripelennamine), ethanolamine derivatives (i.e., doxylamine), and phenothiazine derivatives (i.e., trimeprazine).

Antihistamines antagonize many of the pharmacological effects of histamine by acting as competitive inhibitors of histamine H_1 receptors.

Pyrilamine [*91-84-9*] is marketed as Histavet-P containing 20 mg/mL of pyrilamine maleate and is indicated for use in the horse. The formulation may be administered intravenously, intramuscularly, or subcutaneously.

Pyrilamine

Doxylamine [*496-21-6*] is marketed as A-H Injection containing 11.36 mg/mL of doxylamine succinate for use as an antihistamine in horses, dogs, and cats. It may be administered intravenously to horses and intramuscularly or subcutaneously to dogs, cats, and horses. A-H Tablets contain 100 mg of doxylamine succinate for use as an antihistamine in horses.

Doxylamine

Tripelennamine [*91-81-6*] is marketed as Re-Covr Injection containing 20 mg/mL of tripelennamine hydrochloride for use as an antihistamine in cattle, horses, dogs, and cats. It may be administered intravenously to cattle and intramuscularly to cattle, horses, dogs, and cats.

Tripelennamine

Trimeprazine [*84-96-8*] is a phenothiazine derivative marketed as Temaril-P tablets containing 5 mg of trimeprazine tartrate and 2 mg of prednisolone. The drug is used for the antipruritic and antitussive effects of trimeprazine and the anti-inflammatory effects of prednisolone in dogs.

Trimeprazine

1. Introduction

Legal Definition in the European Union. Vinegar is the product obtained from alcoholic and subsequent acetous fermentation of liquors of agricultural origin (ethanol, wine, cider, perry, or liquors obtained from cereals, including malted barley).

Legal Definition in the United States. In the United States, this definition is extended to include synthetically produced alcohol used for acetous fermentation.

Legal Definition in Japan. Brewed vinegar is a liquid condiment obtained by the acetous fermentation of mash prepared from grains or fruits where alcohol or saccharides may be added.

Use of Synthetic Acetic Acid. Although in Germany a product which has been produced by dilution of acetic acid with water may be called

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a27_403

vinegar, the use of diluted acetic acid for human consumption must be declared as such in all other countries.

2. Physical and Chemical Properties

Vinegar is a clear aqueous liquid, which may be colorless, the color of its raw material, or colored by caramel; the prescribed acetic acid content is 40 – 150 g/L. Further constituents derive from the raw material, added nutrients, or the water used for dilution. Depending on the acetic acid content and the raw material, density, boiling point, freezing point, surface tension, and viscosity differ more or less from the values for pure water; pH is 2.0 – 3.5.

3. Acetic Acid Fermentation

Acetic acid fermentation (acetous fermentation) is an oxidative fermentation in which dilute solutions of ethanol are oxidized by acetic acid bacteria with oxygen from the air to acetic acid and water. Oxidation proceeds according to the basic equation:

$$C_2H_5OH + O_2 \rightarrow CH_3COOH + H_2O$$

$$\Delta G^0 = -455 \text{ kJ/mol}$$

The alcohol-containing solution is called "mash". Its alcohol concentration is given as a percentage by volume. Usually, it also contains some acetic acid, expressed in grams acetic acid per 100 mL (wt/vol %). The sum of ethanol vol % and acetic acid wt/vol % is called the "total concentration" because the sum of these rather incommensurable values gives the maximal concentration of acetic acid which can be obtained by complete fermentation. For details of this curious, but commonly used calculation, see reference [1]. The quotient of the total concentration of the vinegar produced over the total concentration of the mash gives the concentration yield.

4. Raw Materials

All mashes must contain ethanol, water, and nutrients for the acetic acid bacteria.

4.1. Alcohol

By far the largest percentage of vinegar is alcohol vinegar, produced from diluted purified ethanol; other common names are white vinegar or spirit vinegar. It is customary in most countries to denature the ethanol which serves as raw material for the vinegar industry. In most European countries, denaturation is carried out with alcohol vinegar. In the United States it is mostly done with ethyl acetate, which is split into ethanol and acetic acid during fermentation.

Mashes obtained by alcoholic fermentation of natural sugar-containing liquids also serve as raw material. The vinegar is designated according to the particular raw material used. Wine vinegar is produced by acetic acid fermentation of grape wine. Cider vinegar is produced from fermented apple juice. Malt vinegar is made by alcoholic and subsequent acetous fermentation, without distillation, of an infusion of barley malt with or without addition of other cereals, the starch of which has been saccharified exclusively by malted barley diastase. Rice vinegar is made by saccharification of rice starch, followed by alcoholic and acetous fermentation.

4.2. Water

The water used for the preparation of mashes must be clear, colorless, odorless, bacteriologically clean, and without sediments or suspended particles. It must also be free of chlorine, ozone, and other compounds which damage bacteria.

4.3. Nutrients

Most natural raw materials do not require the addition of extra nutrients, but apple cider is usually low in nitrogenous materials. This can be corrected by addition of ammonium phosphate. Some grape wines also require addition of ammonium phosphate for satisfactory fermentation. In rare cases, the same nutrients must be added as for the production of alcohol vinegar.

For the production of alcohol vinegar, a mixture of the required nutrients has been developed. For vinegar with $\leq$15 % acetic acid, acetic acid bacteria require glucose and potassium, sodium, magnesium, calcium, ammonium (as

phosphate, sulfate, and chloride). The following trace minerals are needed: iron, manganese, cobalt, copper, molybdenum, vanadium, and zinc. These additions are sufficient for satisfactory fermentation.

Commercially available mixtures contain supplements, e.g., dried yeast extract, in order to restart fermentation more quickly should it be stopped, e.g., by a power failure. Nutrients should be added sparingly in order to exert a selection pressure on the bacteria.

5. Production

5.1. Microorganisms

5.1.1. Summary and Classification

The microorganisms which oxidize ethanol to acetic acid are commonly called acetic acid bacteria. This special primary microbial metabolism at low pH differentiates them from all other bacteria. Acetic acid bacteria are polymorphous. Cells are gram-negative, ellipsoidal to rod-shaped, straight or slightly curved, 0.6–0.8 µm, occurring singly, in pairs, or chains. There are nonmotile and motile forms, with polar or peritrichous flagella. They are obligately aerobic; some produce pigments, some cellulose.

Attempts to classify acetic acid bacteria up to 1980 have been summarized [1]. At that time, a major contribution to their taxonomy was made by DNA–rRNA hybridization studies [2]. An early conclusion was that the two groups *Gluconobacter* and *Acetobacter*, as classified earlier by DE LEY [3], were closely related, justifying their union in the family Acetobacteraceae, clearly distinguishable as a separate branch in superfamily IV (the α-subclass [4]). Although *Bergey's Manual* [5] gives a set of 32 features to differentiate the genera *Gluconobacter, Acetobacter,* and *Frateuria*, not all of these features are necessary for satisfactory identification.

The characteristic of not overoxidizing acetate identifies the strains from "high-acid" fermentations as members of the genus *Acetobacter*, and thus separates them from the genera *Gluconobacter* and *Frateuria*. SWINGS [6] divided *Acetobacter* into seven species. GILLIS et al. [7] described a species capable of fixing N_2 microaerobically, called *Acetobacter diazotrophicus*.

5.1.2. Required Properties of Industrially Used Strains

Considering the interest that acetic acid bacteria have inspired in microbiologists, it is astonishing how little effect the available information about these bacteria has had on vinegar manufacture. "Working" strains were isolated, but lost again, demonstrating the difficulties of isolating and growing *Acetobacter* strains from industrial vinegar fermentations on solid media.

Considerable progress has been achieved in Japan by propagating bacteria from fermenters on a special double-layer agar. The bacteria isolated on this medium have been described as *Acetobacter polyoxogenes* [8]. However, *A. polyoxogenes* was not available from the Japan Collection of Microorganisms, owing to propagation and preservation problems.

A new species, for which SIEVERS et al. [9] proposed the name *Acetobacter europaeus*, has been isolated and characterized in pure culture from vinegar fermentations at high acidity in Germany and Switzerland. All investigated strains isolated from submerged fermenters and trickle generators had very low (0–22 %) DNA–DNA similarities with traditional strains of *Acetobacter* and *Gluconobacter*. Phenotypic differentiation at species level is rather difficult for *Acetobacter*, since different strains of a single species do not necessarily utilize the same carbon source. A useful criterion for identification of *Acetobacter europaeus* from other *Acetobacter* species is the strong tolerance to the 4–8 % acetic acid contained in AE agar, and the absolute requirement of acetic acid for growth.

Independent of all these problems, the vinegar industry's first requirement is a strain of acetic acid bacteria which: tolerates high concentrations of acetic acid and total concentration; requires small amounts of nutrients; does not overoxidize the acetic acid formed; and yields high production rates. It seems that it is also necessary to make this strain phage resistant [10].

5.1.3. Industrially Used Strains

The vinegar industry has traditionally worked with acetic acid bacteria which are not derived

from pure cultures. The astonishing fact that common microorganisms used on a large scale for industrial vinegar production have not been properly described and characterized in taxonomic terms is due to the difficulty of cultivating them on semisolid media.

Industrial submerged vinegar fermentations are started by treatment with "inoculation vinegar" (microbiologically undefined residues from previous fermentations). Acetic acid fermentation can be carried out for years without interruption or decrease in efficiency or yield, if suitable conditions are chosen to allow a permanent selection of strains which tolerate high acidity and can live on a minimum of nutrients.

It has long been known that the properties of a newly isolated strain of acetic acid bacteria may change from the very first moment of cultivation in Petri dishes, and that this strain, if cultivated over a number of generations, may show other properties, especially in its adaptation to certain concentrations of acetic acid, but also in its phenotypic features.

Investigations using plasmid profile analysis to characterize and identify acetic acid bacteria derived from vinegar fermentations failed to verify this variability.

Plasmid Profile Analysis. Since DAVIES et al. [11] first used plasmid profile analysis for identification of lactic acid bacteria, this method has become a powerful tool to identify and characterize strains of all genera. Plasmids are circular, extrachromosomal DNA molecules, which can be extracted from bacteria. The plasmid profile of one strain is very specific. Plasmids can determine certain properties of bacteria (phage resistance or citrate metabolism).

The potential of this technique for vinegar fermentations has been investigated [12–14]. The majority of acetic acid bacteria contain 1 – 8 plasmids of molecular mass $(1-17)\times 10^6$ or more. SIEVERS et al. [15] used plasmid profile analysis to characterize *Acetobacter europaeus* strains and microflora in industrial vinegar plants. The microflora in submerged fermentations consists of one predominant strain, whereas in trickle generators the microflora is quite heterogeneous, containing a mixture of several *Acetobacter europaeus* strains with quite different plasmid profiles. This is probably the reason for the susceptibility of submerged fermentations to bacteriophage attack. The determination of plasmid profiles from submerged vinegar fermenters represents a new and powerful technique for characterizing the microflora, and answering questions, e.g., on the stability, origin, and identity of the prevailing microflora.

Investigations in the last years showed that the plasmid profiles of these strains can be stable for at least 5 a, and do not change their phenotypic features during this time.

Fermentations at high total concentrations are carried out continuously in the laboratories of Heinrich Frings, Germany, to increase acetic acid tolerance of the strains. Cultures are supplied to vinegar factories in all parts of the world.

In 1993 Frings established a Phage and Plasmid Laboratory for further investigations.

5.1.4. Genetic Improvement

To improve strains of *Acetobacter* genetically, recombinant DNA techniques are considered useful. Host – vector systems and an efficient transformation method for *Acetobacter* have been developed. Preparation of spheroplasts and development of a spheroplast fusion method have been described [16]. A strain growing at 37 °C in 4 % acetic acid and a strain unable to grow at 35 °C in 5 % acetic acid were spheroplasted and fused. Fusants were able to grow at 37 °C on agar plates containing 5 % acetic acid, on which both parent strains were unable to grow.

Genetic transformation systems have been described for *Acetobacter xylinum* [17], *Acetobacter aceti* [18], *Acetobacter* and *Gluconobacter* strains [13], [19–21].

5.1.5. Bacteriophages

Acetobacter -specific bacteriophages demonstrated by electron microscopy in submerged and trickle fermenters have been suspected of causing fermentation problems in industrial vinegar fermenters [14], [22–24]. In trickle generators, fermentation is sometimes slowed down, but rarely stops completely. In submerged fermentations, complete loss of productivity has been observed. Only three morphologically different *Acetobacter* phage types had been described until 1992, when SELLMER et al. [23]

demonstrated a great variety in phage types, regarding the dimensions of the phage heads and tails. All phages isolated from vinegar fermentations in Germany, Austria, and Denmark showed long contractile tails and isometric heads belonging to Bradley's group A [25] and the family Myoviridae [26], respectively. Although not all phages described have actually been shown to be infective for defined *Acetobacter* strains, owing to lack of a suitable technique, their occurrence in high numbers ($10^6 - 10^9$ per milliliter) in disturbed fermentations suggests that bacteriophages may actually be the source of fermentation problems.

5.2. Biochemistry

During acetic acid fermentation, ethanol is almost quantitatively oxidized to acetic acid. Concentration yields of 95 – 98 % are common; the remainder is mainly lost in the effluent gas. At the same time a suitable C_6 carbon source (preferably glucose) is oxidized; end products are CO_2 and H_2O.

5.2.1. Ethanol

Ethanol is oxidized by two sequential reactions catalyzed by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH), which can be located at the outer surface of the cytoplasmic membrane, functionally linked to the respiratory chain of the organism [27], [28]. Alcohol dehydrogenase has been purified from several acetic acid bacteria and shown to contain pyrroloquinoline quinone (PQQ) as well as heme c as prosthetic groups [29], [30]. Extensive purification and characterization of the enzymes involved in ethanol oxidation of *Acetobacter aceti, A. rancens,* and *Gluconobacter suboxydans* have been reported [29–35]. ADH of acetic acid bacteria donates electrons directly to ubiquinone in the cytoplasmic membranes. Thus, the ethanol oxidase respiratory chain of acetic acid bacteria consists of only three membranous respiratory components, alcohol dehydrogenase, ubiquinone, and terminal oxidase [36].

Ameyama et al. [33] confirmed that ADH and ALDH of acetic acid bacteria have the same prosthetic group, PQQ, as glucose dehydrogenase of the bacteria. These quinoproteins – glucose, alcohol, and aldehyde dehydrogenases – are involved in sugar oxidation linked to an electron transport system in the membrane of oxidative bacteria. Fukaya et al. [37] and Tayama et al. [38] purified the ADH and the ALDH from *A. polyoxogenes* sp. nov. This strain was isolated from a vinegar factory; it had higher acid productivity and tolerance to acetic acid than strains isolated from natural sources. In contrast to the ADH and ALDH obtained from *A. aceti* and *G. suboxydans*, the enzymes of *A. polyoxogenes* were quite stable, and this high stability seems at least partially involved in the ability of *A. polyoxogenes* to produce high concentrations of acetic acid.

5.2.2. Sugar

For the breakdown of sugars, *Acetobacter* is equipped with the hexose monophosphate (HMP) pathway and the tricarboxylic acid (TCA) cycle [39], whereas glycolysis is either absent or very weak [40]. The enzymes of the Entner – Doudoroff pathway are present in *Gluconobacter* spp. and in *Acetobacter xylinum* [41]. *Gluconobacter* and *Acetobacter* are known for their direct oxidative capacity on sugars, alcohols, and steroids [42]. For further details see reference [1]. The biochemistry of the ketogenic activities of acetic acid bacteria have been reviewed [43].

5.2.3. Acetate

Strains of *Acetobacter* are able to oxidize acetate as well as lactate in both the presence and absence of ethanol by using enzymes of the TCA cycle.

5.2.4. Carbon Dioxide

It has been known since 1952 that *Acetobacter* needs CO_2 for growth [44]. CO_2 is incorporated into cell substances, where ca. 0.1 % of the cell carbon is derived from CO_2. A very small, but measurable portion of acetic acid is derived from CO_2 metabolism [45].

5.2.5. Nitrogen

If an organic carbon source is present, a number of acetic acid bacteria can use ammonium ions as the sole nitrogen source. Other strains need the presence of amino acids, others need cofactors, e.g., vitamins or purines [46]. No essential amino acids are known.

5.2.6. Growth Factors

The growth factor requirement depends on the carbon source [47]. Some strains require *p*-aminobenzoic acid, niacin, thiamin, or pantothenic acid as growth factors [48]. Ameyama and Kondo [49] found that some *Acetobacter* strains did not need vitamins in the presence of glucose. But the combined addition of glutathione and sodium glutamate had a cumulative effect on the growth of *A. aceti* [50].

The novel prosthetic group in acetic acid bacteria, PQQ, also shows an interesting growth stimulating effect on various microorganisms [50–52]. There are two PQQ effects:

1) Stimulation of both growth rate and total cell yield with only a trace amount of PQQ as an essential growth factor
2) A marked reduction of the lag phase in microbial growth, but with no increase in growth rate in the subsequent exponential phase, or in total cell yield in the stationary phase

PQQ is produced in culture media by most strains of microorganisms.

5.3. Physiology

5.3.1. Oxygen Demand and Total Concentration

During commercial use of many aerobic microorganisms, it is common to permit the inoculum to remain in the fermenter for several days without aeration, before inoculation into the main fermenter. However, this procedure is unthinkable in the case of acetic acid fermentation.

Extensive tests have been conducted [53], [54] on the damage to acetic acid bacteria by interruption of aeration as a function of total concentration, acetic acid concentration, rate of fermentation, and length of the interruption. The longer the interruption of aeration and the higher the total concentration of the mash, the more marked the effect. At total concentration 5 %, an interruption of aeration for 2 – 8 min leads to the same damage as an interruption of 15 – 60 s at total concentration 11 – 12 %. At constant total concentrations, damage increases with increasing concentration of acetic acid, and with increasing fermentation rate. The specific production of cell material is extremely low. For more details see reference [1].

Muraoka at al. [55] confirmed these results. There was a sharp drop in ethanol oxidation rate as well as in the activity of the enzymes involved (ADH and ALDH) after an interruption of the oxygen supply, with acetic acid concentration 6 %. The ADH activity in the membrane fraction was highly stable in culture broth containing $\leq$4 % acetic acid, but the purified enzyme was very unstable, even in a culture broth of 2 % total concentration. It was suggested that ADH has a membrane component contributing to its stability up to 4 % acetic acid, which becomes gradually liable to damage with further increasing acidity. The relation of the ADH system to oxygen has not been elucidated.

Under conditions of industrial acetic acid production, the microorganisms undergo considerable stress, caused by a high concentration of acetic acid and limited oxygen supply. A high utilization of oxygen, up to 70 %, can be achieved in industrial production. A sparing use of air is very important, because of the volatility of ethanol and acetic acid. However, the use of pure oxygen or highly oxygen-enriched air may damage the bacteria [53].

Hitschmann and Stockinger [56] found that, at a total concentration of 13 %, ATP content of the cell and growth show reverse behavior. The energy charge (average value of intracellular ATP, ADP, and AMP) showed a rather high value of 0.84 at the beginning of fermentation. During fermentation, while the acetic acid concentration increased from 9 to 12 %, the energy charge decreased to 0.7. After 45 s interruption of aeration, the energy charge dropped to 0.58, and after several weeks of storage, the charge of the inoculum was 0.50.

5.3.2. Lack of Ethanol

Acetic acid bacteria are also damaged if vinegar fermentation is carried out to the point where all the ethanol has been oxidized, and the addition of fresh ethanol-containing mash is delayed. This is analogous to the damage resulting from interruption of the oxygen supply, and also depends primarily on the total concentration and the duration of the ethanol shortage.

5.3.3. Specific Growth Rate

Hromatka et al. [57] were the first to calculate the specific growth rate of acetic acid bacteria. In semicontinuous fermentations, the specific growth rate did not decrease at increasing acetic acid concentrations, but at increasing total concentrations it decreased from $0.49\,h^{-1}$ at 5 % to $0.16\,h^{-1}$ at 11 %.

In a continuous culture at total concentration 12 %, the specific growth rate decreased from $0.027\,h^{-1}$ at 4.5 % ethanol to $0.006\,h^{-1}$ at 1 % ethanol. The specific growth rates obtained in continuous fermentations with constant acetic acid and ethanol concentrations are less favorable than those obtained under semicontinuous conditions.

Vera and Wang [58] carried out batch fermentations with *Acetobacter suboxydans*, and showed, at a total concentration of 7.5 %, a specific growth rate of $0.30\,h^{-1}$, in good agreement with the findings of Hromatka et al. [57].

5.3.4. Specific Product Formation

Hromatka and Ebner [59] found a specific product formation of 21 g acetic acid per gram bacterial dry substance per hour in semicontinuous tests at total concentration 10 %. This very high value was independent of acetic acid concentration from 4.5 to 7.2 %. Mori and Terui [60] found a strong dependence of specific product formation on acetic acid concentration in continuous fermentations at total concentration 7 %. The maximum specific product formation was $15\,g\,g^{-1}\,h^{-1}$. Vera and Wang [58] found that specific product formation follows a growth-associated mechanism as long as the acetic acid concentration is <3 %. At higher acetic acid concentrations, up to 7 %, an additional non-growth-associated term must be considered. The highest value obtained with cell recycle in continuous culture of *A. suboxydans* was $11.5\,g\,g^{-1}\,h^{-1}$.

5.3.5. Concentration and Temperature

When a fermentation is charged with mash, this must be done at the same total concentration under rapid mixing, because a locally high concentration gradient damages the bacteria. The next cycle starts with no lag phase. The temperature has to be kept constant because a repeated change in temperature causes a similar result [1].

5.3.6. Overoxidation

Overoxidation is the undesirable oxidation of acetic acid to CO_2 and H_2O. To prevent it, lack of ethanol must be avoided, and the total concentration should be kept high. In trickle fermenters, this is much more difficult than in submerged fermenters [1].

5.4. Industrial Processes

5.4.1. Submerged Vinegar Fermentation

5.4.1.1. Semicontinuous and Continuous Fermentations

For production of vinegar with 12 – 15 % acetic acid, the process has to be be carried out in a semicontinuous manner [61], fermentation cycles taking about equal amounts of time. The starting concentration of each cycle is 7 – 10 % acetic acid and ca. 5 % ethanol. When an alcohol concentration of 0.05 – 0.3 % has been reached in the fermenting liquid, a quantity of vinegar is discharged from the fermenter, so that refilling with new mash of 0 – 2 % acetic acid and 12 – 15 % alcohol restores the same starting concentrations for the new cycle. Discharging must be carried out quickly to avoid complete depletion of alcohol. Charging must be slow, under constant fermentation temperature and rapid mixing.

By the end of 1993 it was possible to produce vinegar of up to 17.5 % acetic acid in a modified

single-stage process. Starting with similar concentrations as above, alcohol is slowly added at a constant concentration of 2 – 3 % alcohol during a corresponding increase of total concentration. When alcohol approaches zero, part of the fermenter contents is discharged and replaced by mash with lower total concentration, to bring acetic acid and total concentration back to starting conditions, enabling the bacteria to multiply faster. Later, total concentration is increased again, by adding alcohol.

Continuous fermentation is possible up to 9 –10 % acetic acid only because the specific growth rate of the bacteria decreases with decreasing ethanol concentration; to obtain a high yield, fermentation must be carried out at low alcohol concentration.

5.4.1.2. Two-Stage Processes

The canning industry requires vinegar with a very high percentage of acetic acid. The vinegar industry is interested in producing vinegar of high acidity to save storage and transport costs. In 1978, a two-stage process for the production of vinegar with >15 % acetic acid was developed [62]. During submerged fermentation with total concentration <15 % in a first fermenter, alcohol is added slowly to increase the total concentration to ca. 18.5 %. When the acetic acid concentration has reached 15 %, ca. 30 % of the fermenting liquid is transferred to a second fermenter. The first fermenter is resupplied with new mash of lower total concentration. In the second fermenter, fermentation continues until the alcohol is almost depleted. The whole quantity of the finished vinegar is discharged. The fermenting liquid in the first fermenter is supplied with alcohol at the appropriate time, and later divided again.

Vinegar of >20 % acetic acid can be produced by this process. Automatic control for the process has been described [63].

In 1980, a similar two-stage process for the production of vinegar with >20 % acetic acid was described [64], [65], where the second fermentation stage is carried out at only 18 – 24 °C, while the first fermentation stage uses the normal temperature range of 27 – 32 °C.

Maselli and Horwath [66] reported a similar two-stage process with semicontinuous fermentation in at least two fermenters and membrane filtration of the mash from the semicontinuous stage, after combining it with an oxygen-containing gas. After the addition of ethanol and nutrients, the concentrated mash with the bacteria is subjected to batch fermentation at a substantially lower temperature until 18 – 20 % acetic acid is reached. The membranefiltered vinegar is used as the second end product.

5.4.1.3. The Frings Acetator

The Frings Acetator is the most common equipment for the production of all kinds of vinegar. At the end of 1993, >600 acetators were in operation worldwide, with total annual production 1354×10^6 L vinegar with 10 % acetic acid. Energy consumption is ca. 400 W per liter fermented ethanol, and the yield is up to 98 %.

Commercial acetators ferment up to 3600 L pure ethanol in 24 h.

The different processes demand excellent performance of the fermenter, especially of its aeration system.

The Frings Aerator [67] is self-aspirating; no compressed air is needed. The rotor is installed on the shaft of a motor mounted under the fermenter, connected to an air suction pipe, and surrounded by a stator. It sucks air and pumps liquid, creating an air – liquid emulsion which is ejected through the stator, radially outward at a given speed, chosen so that the turbulence of the stream causes a uniform distribution of the air over the whole cross section of the fermenter.

As foam formation cannot always be avoided, the Acetator is equipped with a mechanical defoamer. From 1966 to 1991, the equipment described by Ebner [68] was used. The rotor, turning in a spiral housing, separates liquid and gas, and returns the liquid to the lower part of the fermenter. Only during discharging of the finished vinegar is part of this returned liquid pumped out of the fermenter. As this liquid causes foam formation, the defoamer must operate during most of the fermentation cycle. Wittler [69] described an improvement where the separated liquid portion is not pumped back into the fermenter, but into a small collecting vessel, to be later admixed with the vinegar end product. Lysis of harmed vinegar bacteria releases foam, forming surface-active substances. By total elimination of the separated liquid, further

foam buildup is avoided. Minimal foam formation with shorter operating time of the defoamer, and consequently lower power uptake and negligibly small volume of separated liquid are the result.

The Frings Alkograph [70], an automatic instrument for measuring the amount of ethanol in the fermenting liquid, has been in use since 1965. Small amounts of liquid flow continuously through the analyzer, first through a heating vessel, and then through three boiling vessels. The boiling temperature of the incoming liquid is measured in the first boiling vessel. While alcohol is distilled off continuously from the second and third boiling vessels, the higher boiling point of the liquid from which ethanol has been removed is measured in the third boiling vessel. The difference in temperature corresponds to the ethanol content, and is recorded automatically. As flow through the vessels takes some time, there is a delay of about 15 min between the beginning of sample inflow and the time when the right value is shown on the recorder. As alcohol concentration decreases slowly during fermentation, this delay has no adverse effect on fermentation control.

To carry out the single-stage semicontinuous process, a contact in the Alkograph activates the vinegar discharge pump when a defined alcohol content is reached. As soon as a preset level has been reached, the mash pump starts adding fresh mash. This pump is controlled by the fermentation temperature, in order to refill at constant temperature. The pump is stopped when the desired level is reached, and an automatic cooling system is activated. A fermentation cycle takes 24 – 48 h.

The Alkograph has worked with great reliability for ca. 30 a in 231 acetators around the world. New biosensors, together with modern membranes, have permitted the development of a device to measure alcohol with no time delay – the Frings Alkosens. Heider et al. [71] described a device for measuring volatile constituents of the fermentation medium. A membrane serves to filter them from the fermenting liquid into a carrier medium, and an electronic sensor responds to these volatile constituents. As the measurement relies on diffusion, ambient temperature has to be maintained at the same level. Thus, the alcohol probe is situated in the fermentation broth. The alcohol value shown at the analyzer is influenced by the concentration of acetic acid, and new calibrations are needed at different total concentrations. This disadvantage has been overcome by the Frings Alkosens II, which incorporates a multilayer membrane. New sensor technologies and more sophisticated computer equipment permit fully automated process control of continuous, semicontinuous, as well as single- or two-stage high-strength fermentations, including preparation of the mash.

5.4.1.4. Further Trends in Submerged Processes

Hekmat et al. [72] applied a computerized experimental system to submerged acetic acid fermentation with industrial *Acetobacter* strains at ca. 10 % final acidity, using automated semicontinuous cycles over a period of 1 a. Based on these data, a mathematical model was developed, which could predict the time course of a cycle, even if a lag phase occurred at the beginning of the cycle, owing to a lack of substrate at the end of the previous cycle. The parameters substrate, product, and biomass are not sufficient to characterize the physiological status of the culture, since the behavior of the microorganisms also depends on their history. The RNA concentration per unit of cell mass was found to be a key internal component of the microorganisms, permitting reasonable agreement between the experimental data and the mathematical model.

Mori [73] summarized the possibilities for on-line measurement of alcohol concentration in vinegar production – the Frings Alkograph and Alcolyzer, a Japanese instrument based on the same principle, immobilized microbial sensors, immobilized enzyme sensors, and semiconductor alcohol sensors.

Nomura et al. [74–76] reported experiments on the continuous production of acetic acid by submerged fermentation with continuous removal of acetic acid by electrodialysis, continuous supply of ethanol and concentrated nutrient solution, with control of ethanol and pH. The ethanol concentration was kept constant at 1 %, acetic acid concentration ca. 2 %. Without dialysis and pH control, acetic acid production stopped after 2 d around 4 %, while with dialysis it lasted 30 d.

5.4.1.5. Other Submerged Fermentation Processes

Other processes of little practical significance and abandoned processes are described in reference [1].

5.4.1.6. Continuous Culture and Cell Recycle

Much work has been invested in increasing the productivity of acetic acid fermentation by continuous culture and cell recycle [58], [77].

At first sight, productivity in an acetator does not seem very high, e.g., in a fermenting volume of 100 m^3 4000 kg acetic acid in 24 h at a concentration up to 15 % (1.6 g L^{-1} h^{-1} on average, or ca. 2.4 g L^{-1} h^{-1} at maximum fermentation rate). The aeration rate is only 0.1 vvm (vvm denotes volume of gas per volume of liquid per minute); nutrient consumption is as described in Section 4.3.

Kinetic studies [77] have clarified the dependence of bacterial growth rate on ethanol concentration, acetic acid concentration, and concentration of dissolved oxygen; optimum values are: ethanol 23 g/L; acetic acid 36 g/L; and oxygen 2.5 – 3 mg/L. The productivity of acetic acid formation depends not only on the growth rate, but also on the cell concentration; the maximum productivity of 6 – 6.6 g L^{-1} h^{-1} occurs at ethanol 32 g/L and acetic acid 60 – 66 g/L.

Nanba et al. [78] studied the synergistic effects of acetic acid and ethanol on the growth of *Acetobacter* spp. at low concentrations, with similar results. The possible productivity is at first sight about four times higher than presently reached, and could be further increased by recycling the bacteria, but this high degree of productivity is possible only over a narrow range of concentrations. A slight change of ethanol, acetic acid, or oxygen concentration means an immediate return to lower values.

A second fermenter connected in series to the main fermenter would be necessary to complete the fermentation. To maintain the high oxygen concentration in the fermenting liquid at the higher fermentation rate, a high aeration rate would be necessary, with recovery of ethanol and acetic acid from the exhaust gas to obtain high yields; addition of oxygen would probably also be necessary. Higher nutrient consumption and increasing foam difficulties would result. The cell recycle system would need continuous microfiltration to avoid a lack of oxygen, which would harm the bacteria, and automatic control of cell concentration. The considerable expenditure on process control would merely allow production of the same amount of vinegar with $\leq$10 % acetic acid in a smaller fermenter. High productivity is not necessarily the right path to follow.

Park et al. [79], [80] tried to improve continuous acetic acid production in a laboratory fermenter equipped with a hollow fiber filter module by increasing the concentration of dissolved oxygen. The maximum acetic acid concentration reached was 5 %. The highest productivity obtained with yeast extract as nutrient was 107 g L^{-1} h^{-1}. The dissolved oxygen concentration was already lower than the critical concentration of 1 ppm, although pure oxygen was supplied at an aeration rate of 1 vvm. Furthermore, it was difficult to maintain a high concentration of viable cells in the cell recycle culture, because the cells were inactivated by the lethal conditions of acetic acid concentration, oxygen deficiency, and nutritional limitation. The effect of dissolved oxygen and acetic acid concentration on acetic acid production in continuous culture has been extensively investigated [81]. The optimum concentration of dissolved oxygen was ca. 2 ppm for acetic acid production at low acidity. But the specific acetic acid production rate was reduced to zero when the dissolved oxygen concentration was $>$2 ppm at acetic acid concentration $>$4.5 %. This is in good agreement with the fact that using pure oxygen during fermentation may completely inhibit formation of acetic acid [53].

Viability is important for high productivity, and factors affecting it have been investigated [82]. To investigate the effect of cell bleeding (withdrawal at constant flow rate) serial experiments were conducted in a bioreactor with cell recycle, and supported by mathematical analysis. Acetic acid concentrations were up to 5.6 %. Maximum productivity was 123 g L^{-1} h^{-1}. The bleed ratio and dilution rate at which concentrations of acetic acid and viable cells are relatively high can now be predicted. These results should be useful for designing a two-stage culture for acetic acid production, using the active cells in

the bleed from the first stage in a second-stage vessel beyond a lethal acetic acid concentration.

How far these results may influence the construction of industrial equipment in Japan remains to be seen. The costs of such complicated fermenters may prevent a rapid conversion to the industrial scale, although in Japan the amount of vinegar with 5 % acetic acid is relatively high. But these results are unlikely to influence the production of vinegar with more than 10 % acetic acid. A review of the Japanese development work states that the scale-up problem remains to be investigated [83].

5.4.1.7. Semicontinuous Culture and Cell Recycle

Park et al. [84] investigated semicontinuous cultures with cell recycle, and found an increase in productivity compared with semicontinuous culture without cell recycle at acidity up to 6 %. While the concentration of total cells increased in every cycle, the viable cells reached a much lower quasi-steady value, which was explained by product inhibition. Productivity was $2.9\,g\,L^{-1}\,h^{-1}$ without, and $5.0\,g\,L^{-1}\,h^{-1}$ with cell recycle at 6 % final acetic acid concentration, but $14\,g\,L^{-1}\,h^{-1}$ at 3 %.

In another study Park et al. [85] reported semicontinuous fermentations in which the ethanol concentration was held for a time between 20 and 30 g/L, by adding ethanol-rich medium. At the end of the cycle ethanol-poor medium was added. Cells were recycled by membrane filtration. The object was to obtain high concentrations of acetic acid. The highest value reached was 9 %. *Acetobacter* cells lost viability at about 6 % acetic acid, but nonviable cells were still effective for ethanol oxidation. Ebner had noted this interesting feature of *Acetobacter* cells in 1976 [86].

5.4.2. Surface Fermentation

5.4.2.1. History

Conner and Allgeier [87] have described the history of vinegar fermentation; equipment used in the famous Orleans process for the production of wine vinegar can be seen only in museums.

5.4.2.2. New Experiments with Surface Fermentation

A new approach to surface fermentation has been tried [88]. It uses a bioreactor with a shallow, horizontal flow of medium, under a bacterial film of a few hundred cm^2 surface area. Liquid depth is up to 10 mm and the acetic acid concentration of the effluent 5.76 %. The oxygen absorption rate through the microbial film is very high [89] and a kinetic study of the acetic acid production has been published [90].

A surface fermentation process in a system of series-intercommunicating fermentation vessels, with flow regulation to approximate plug flow, has been described [91]. Liquid depth under the layer of acetic acid bacteria was ca. 50 mm. The inflowing liquid had 2 % acidity and 3.5 % alcohol. The acidity of the effluent stabilized at 5 % acetic acid. The residence time was ca. 21 h.

Higashide et al. [92] reported continuous surface fermentations in a single vessel with 16 L working volume. Under optimum conditions, with a broth depth of 100 mm, 2 – 3 % acidity, and 20 – 30 g/L alcohol concentration of the inflowing liquid, vinegar with 4.5 % acetic acid was produced for 80 d. The flavor was claimed to be better than that of vinegar produced by other processes.

For the production of high-quality rice vinegar in Japan, surface fermentation has been developed to an automatic process at lower cost.

5.4.3. Trickle Processes

The old, semicontinuous generator process used beech wood shavings, birch twigs, or corn cobs as carrier material for the vinegar bacteria. Large wooden tanks with up to $100\,m^3$ shavings are still in use. The fermenting liquid is collected in the lower part of the tank, and pumped continuously under cooling over the carrier column. Air is aspirated or ventilators are installed. Generators more than 40 years old are still producing.

The inhomogeneity of the carrier column makes it impossible to distribute the air and the trickling liquid as homogeneously as desired. Variations in temperature within the column can hardly be avoided. Mashes containing

high amounts of nutrients and low in total concentration form slimy deposits in the carrier material which may clog the column.

Nevertheless, the use of a silicate carrier material with large specific inner surface area and an open pore structure has been proposed [93].

5.4.4. Experiments with Immobilized Acetic Acid Bacteria

Many Japanese scientists have investigated the fermentation of rice or fruit vinegar at the usual strength of ca. 5 % acetic acid in continuous fermentation at high productivity with immobilized acetic acid bacteria.

Mori et al. [94] reported a 460-d run in an airlift bioreactor with acetic acid bacteria immobilized on κ-carrageenan gel beads, where living cells were newly released into the reactor. These newly released bacteria had an extremely high growth rate and respiratory activity, which they retained for a few generations after leakage. The fact that bacteria, entrapped in a κ-carrageenan gel and treated in a fluidized bed reactor were gradually released from the gel beads, was already known [95].

Okuhara [96] and Nanba et al. [97] proposed polypropylene fibers as carrier material for *Acetobacter* producing rice vinegar with 3 % acetic acid. Kondo et al. [98] used a ceramic honeycomb monolith as carrier in a fixed-bed reactor, and reached a maximum of 4 % acetic acid. Saeki [99] investigated calcium alginate beads in a fluidized bed reactor, and obtained 3.5 % acetic acid. This reactor has been used in combination with an ethanol fermenter to produce rice vinegar of up to 6.5 % acetic acid from a saccharified rice medium [100], [101].

Takada and Hiramitsu [102] tested a two-column, porous ceramic bioreactor to produce vinegar from orange wine with up to 8.4 % acetic acid. Yamashita et al. [103] fixed the cells on woven cotton fabric to produce vinegar from kiwi fruit and persimmon with 4.5 % acetic acid. Because of the disadvantages of all known carriers, Sueki et al. [104] tried a new ceramic carrier, Aphrocell, with a continuous pore structure, but the oxygen supply to its structure was difficult. None of the tested carriers was ideal.

Sun et al. [105] carried out experimental and theoretical studies on continuous acetic acid production by immobilized cells in a three-phase fluidized bed bioreactor at very low acetic acid concentrations. The effects of gel-entrapped and suspended cells, gel size, volumetric mass transfer coefficient of oxygen ($k_L\,a$), and solid holdup on productivity were studied by theoretical calculations and experiments.

Immobilized acetic acid bacteria are highly oxygen dependent [106–108]; it is advantageous to supply oxygen to a closed and pressurized culture. Feeding medium at a higher dilution rate gives a higher production rate. As acetic acid inhibits the bacteria, multiple reactors in series should be the best means of increasing acidity, thereby keeping the dilution rate higher and creating the necessary prolonged residence time. An output acidity of 5.5 % was obtained in two bench-scale fluidized bed reactors in series. In scaling up to a pilot reactor, carrageenan gel beads were not used as they tended to break up. Porous chitosan beads were selected, diameter 0.3 – 3 mm, giving a higher productivity, up to 9 g L^{-1} h^{-1}, but the microbial layer was easily peeled off. More operational experience is needed for the practical application of this technology.

5.4.5. Environmental Protection

Vinegar can be produced without environmental pollution. The exhaust gas contains alcohol, acetic acid, and ethyl acetate according to their vapor pressures at fermentation temperature ca. 30 °C. To obtain high yields, the aeration rate is kept as low as possible. It is common practice to cool the exhaust gas with water and, in order to absorb the rest of the volatiles, it can be scrubbed with water, which is recycled and later used for mash preparation.

The raw vinegar contains bacteria which must be filtered off. Most modern factories use cross-flow filtration without any filter aid. The very small quantity of remaining solids (ca. 100 g per 1000 L vinegar) formed by the acetic acid bacteria, is degraded during wastewater treatment.

5.5. Treatment of Raw Vinegar

Vinegar produced by one of these processes is called "raw vinegar". It contains <0.5 % alcohol

and, depending on the raw material, up to 20 % acetic acid. It is more or less turbid as it contains acetic acid bacteria and deposits which originate from the raw material; prior to consumption, it needs further treatment.

5.5.1. Storage and Quality

In the course of acetous fermentation, the pH of the fermenting mash is reduced. Vinegars obtained from natural raw material are unstable with regard to the solubility of previously dissolved substances. This lability lasts longer, for lower values of the pH change during fermentation. A freshly produced cider vinegar may need months to stabilize. Alcohol vinegar does not show this instability. Vinegar for storage should preferably be undiluted, as discharged from the fermenter. In storage the quality improves, especially important for all types of wine vinegar. The aging of wine vinegar comprises many complicated reactions [109]. Vinegar must have a pure aroma which imparts the flavor of the raw material.

5.5.2. Filtration

The traditional methods of vinegar clarification by fining and precoat filtration are still in use [110]. Micro- and ultrafiltration are gaining ever-increasing market shares in the large European and American factories.

The basic principle of the first long-term ultrafiltration process for vinegar, which was performed in the Frings stream filter, has been described in detail [110], and further improvements have been made [111].

Vinegar is a cheap substance, so filter costs have to be low, and repeated long-term use of the filter modules is important. The unavoidable formation of a film on the membrane (reducing the filtration rate) must be delayed as long as possible. Easy, repeated and mainly automatic cleaning of the membrane is also important. A cross-flow filter, partly fulfilling these requirements, may be more or less suitable for the filtration of vinegar.

5.5.3. Pasteurization

Wine vinegars are frequently unstable, owing to enzymes and microorganisms which may later cause cloudiness in bottle. To avoid this, vinegar is pasteurized before or after bottling. Heating to 75 – 80 °C for 30 – 40 s, or to 50 – 55 °C for longer periods is common [110].

5.5.4. Bottling and Shelf Life

Vinegar for household use is filled into glass or polyethylene bottles, sealed with plastic screw caps. Air tightness is essential to guarantee preservation. Filtered spirit vinegar does not present great difficulties, but all wine vinegars do. Institutional users such as restaurants or hospitals often get their vinegar in plastic containers of ca. 25 L, industrial users in stainless steel tank cars.

6. Constituents of Vinegar

Besides acetic acid and ethanol, vinegar contains secondary constituents which play an important role in its smell, taste, and preserving qualities. These constituents have their origin in the raw material, in added nutrients, and in the water used for dilution. They are also formed by acetic acid bacteria or by interaction of the components of the vinegar.

Spirit Vinegar. Schanderl and Staudenmeyer [112] discovered 8 amino acids in a spirit vinegar produced by submerged fermentation, where only glucose and inorganic salts had been added as nutrients; Bergner and Petri [113–115] increased the number of amino acids found in spirit vinegar to 18. According to Petri [116] these are mainly products of autolysis of the acetic acid bacteria. Aurand et al. [117] and Kahn et al. [118], [119] identified 27 volatile compounds in an ether – pentane extract of neutralized spirit vinegar; more details are given in reference [110].

Wine Vinegar. Wine vinegars contain the same spectrum of amino acids as spirit vinegar, but in larger amounts. During acetous fermentation, acetylmethylcarbinol develops in varying

quantities [120], [121]. In an ether – pentane extract of wine vinegar, KAHN et al. [119] identified 42 compounds; more details are given in reference [110].

Cider Vinegar. KAHN et al. [118], [119] identified 33 compounds in the ether – pentane extract of cider vinegar, and only a few were found in the cider from which the vinegar was made. The compounds correspond approximately to those found in wine vinegar.

Malt Vinegar. JONES and GREENSHIELDS [122], [123] identified 6 esters, 6 alcohols, 2 acids, acetoin, and acetaldehyde in malt vinegar. KAHN et al. [119] found 54 compounds in malt vinegar, including halogen compounds which obviously originated from the raw material.

Rice Vinegar. MAEKAWA and KODAMA [124] identified 5 phenolic acids in rice vinegar. YANAGIDA et al. [125] found that the percentage of amino acids in rice wine decreased during acetous fermentation. KOIZUMI et al. [126] compared the free amino acids, organic acids, and aroma components in Chinese vinegars with those of Japanese rice vinegars. The Chinese vinegars were rich in alanine, glutamic acid, lysine, and leucine, in amounts ca. 10 times higher than in Japanese rice vinegar. In Chinese vinegars, lactic acid and pyroglutamic acid were the most dominant acids besides acetic acid. High levels of *n*-propyl alcohol, isobutyl alcohol, acetoin, diacetyl, *n*-butylacetate, ethylacetate, and furfural were detected among the aroma components.

Whey Vinegar. BOURGEOIS [127] analyzed the amino acids of whey vinegar; HADORN and ZÜRCHER [128] determined the specific compounds for its characterization.

7. Analysis of Vinegar

Vinegar is analyzed for process control by general routine methods, and for a comprehensive knowledge of its chemical constituents by special methods. The latter is needed to distinguish between vinegar made by fermentation and diluted synthetic acid, and between true wine or fruit vinegar and blends of such vinegars with spirit vinegar or acetic acid; older methods are described in reference [110].

Newly developed methods offer promising results. Authentication of the origin of vinegars is determined by modern isotopic methods [129]. Initial results demonstrated the ability to detect added synthetic acid, and to establish the botanical origin of the raw materials. It is now possible not only to determine whether the vinegar is made from wine, apples, malt, cane, or beets, but also to determine the country, and even the region, of the raw material. The detection threshold of adulteration with synthetic acetic acid of vinegar of known or unknown geographic origin is 5 and 10 %, respectively. The detection threshold for alcohol vinegar added to wine vinegar of known or unknown geographic origin is 10 and 20 %, respectively.

8. Use of Vinegar

NUNHEIMER and FABIAN [130] found that acetic acid, compared with citric, lactic, malic, and tartaric acids, is a stronger growth inhibitor of microorganisms at higher pH. SZAKALL [131] stated that vinegar has a specific, inhibitory effect on the growth of microorganisms, compared with diluted acetic acid, whose effect is a function of acid concentration only; the reason is as yet unknown.

Household vinegar is mainly used to dress salads. The food industry makes use of the long-familiar ability of vinegar to preserve and season food. The most important preserved vegetables prepared with vinegar are gherkins, onions, red beets, and peppers, in the form of pickles and relishes. Vinegar is an important ingredient in mustard, tomato ketchup, Worcester sauce, mayonnaise, and salad dressings. Fish and meat are also preserved with vinegar.

9. Economic Aspects

European Union. In 1992 the European Union produced 325×10^6 L of alcohol vinegar, 143×10^6 L of wine vinegar, and 45×10^6 L of other vinegars (all at 10 % acetic acid).

United States. The United States vinegar industry no longer publishes production figures, so older figures from the U.S. Department of Commerce's Census of Manufacturers must be quoted here. Production volumes in 1987 were 581×10^6 L distilled vinegar, 54×10^6 L cider vinegar, and 126×10^6 L other vinegars, all of different strength.

Japan. In 1992, Japan produced 56×10^6 L of rice vinegar, 146×10^6 L of other grain vinegars, and 161×10^6 L of other brewed vinegars, in total 394×10^6 L, at a concentration of 4 – 5 % acetic acid.

Worldwide. From statistics and personal knowledge of the situation in many countries, annual world production (excluding the former Soviet Union and China) of vinegar at 10 % acetic acid is assumed to be ca. 1900×10^6 L, or 190 000 t pure acetic acid.

1. Introduction

The first vinyl esters, vinyl trichloroacetate and vinyl acetate, were prepared by KLATTE in 1912 by treatment of acetylene with the corresponding carboxylic acid and mercury salts as catalyst. Initially, the reaction was used for the industrial production of vinyl chloroacetate. The polymer obtained from this vinyl ester was used during World War I as a varnish for airplanes. Vinyl acetate is the most important vinyl ester. Vinyl propionate and vinyl esters of higher carboxylic acids are now also produced industrially (see Chap. 3 and 4).

2. Vinyl Acetate

2.1. Properties

Physical Properties. Vinyl acetate [*108-05-4*], $CH_3CO_2CH{=}CH_2$, M_r86.09, is a colorless, flammable liquid with a characteristic, slightly pungent odor, *bp* 72.8 °C, density at 20 °C 0.932 g/mL, *mp* −93.2 °C, viscosity 0.43 mPA · s, vapor pressure 12 kPa at 20 °C, 42.6 kPa at 50 °C, coefficient of cubic expansion 0.0014 K^{-1}, flashpoint − 8 °C, ignition temperature 385 °C. Lower/upper flammability limits in air 2.3/13.4 vol %, ignition group (VDE 0165) G 2, specific heat 1.926 kJ/kg; heat of evaporation 379.3 kJ/kg at 72.7 °C, heat of combustion 2082.0 kJ/mol, refractive index n_D^{20} 1.3956, heat of polymerization 1035.8 kJ/kg, solubility of water in vinyl acetate 0.9 wt % at 20 °C, solubility of vinyl acetate in water 2.3 wt % at 20 °C, azeotrope with water *bp* 66 °C/100 kPa, water content 7.3 wt %.

Chemical Properties. The chemical property which is exploited almost exclusively is the capacity to polymerize (see Section 2.4).

Other reactions of vinyl acetate: halogens give 1,2-dihaloethyl acetates [6], hydrogen halides give 1-haloethyl acetates [7], acetic acid gives ethylidene diacetate (see Section 2.2), hydrogen cyanide gives 2-acetoxypropionitrile [8], hydrogen peroxide gives hydroxyacetaldehyde [9], and dienes, such as butadiene or cyclopentadiene, give Diels – Alder products [10].

Transesterification with carboxylic acids produces the corresponding vinyl carboxylate and acetic acid [11] (see also Section 2.3) and with alcohols gives the corresponding acetate and acetaldehyde. Thermal cleavage gives ketene and acetaldehyde [12]. Acid-catalyzed [13] or thermal [14] hydrolysis produces acetaldehyde and acetic acid. Vinyl acetate can be epoxidized with peracetic acid (84 % yield)

[15]. It undergoes addition of H-active compounds, e.g., dimethyl phosphite gives dimethyl acetoxyethylphosphonate [16].

2.2. Production

There are various possible routes for vinyl acetate production:

1) Addition of acetic acid to acetylene:
   a) in the liquid phase in the presence of homogeneous mercury salt catalysts
   b) in the gas phase in the presence of heterogeneous catalysts containing zinc salts
2) Addition of acetic anhydride to acetaldehyde giving ethylidene diacetate, and subsequent cleavage of the latter to form vinyl acetate and acetic acid
3) Reaction of ethylene with acetic acid and oxygen
   a) in the liquid phase in the presence of palladium/copper salts as homogeneous catalysts
   b) in the gas phase on heterogeneous catalysts containing palladium
4) Reaction of methyl acetate or dimethyl ether with carbon monoxide and hydrogen in the liquid phase in the presence of homogeneous catalysts, e.g., rhodium salts or noble metals of the platinum group, giving ethylidene diacetate; cleavage of the latter giving acetic acid and vinyl acetate

Acetylene, which is expensive, has mostly been replaced by the cheaper alternative, ethylene; ca. 80 % of the available capacity is used for process 3 b and ca. 20 % for process 1 b.

Processes 1 a, 2, and 3 a are no longer used, while process 4, although allegedly developed to an industrial level, has not yet been used industrially. It may become more important because the starting materials can readily be produced from coal or naphtha.

2.2.1. Addition of Acetic Acid to Acetylene

Liquid-Phase Process The addition of carboxylic acids to acetylene using mercury salts as the catalyst [17]

$$CH_3CO_2H + CH{\equiv}CH \xrightarrow[\text{Hg salts}]{60-100\,^\circ C} CH_3CO_2CH{=}CH_2 \qquad \Delta H = -117\ \text{kJ/mol}$$

is now of historical interest only. For more details see [18], [19].

Gas Phase Process

$$CH{\equiv}CH + CH_3CO_2H \xrightarrow[\text{zinc acetate on activated charcoal}]{160-210\,^\circ C} CH_3CO_2CH{=}CH_2 \qquad \Delta H = -117\ \text{kJ/mol}$$

The first process was developed in Munich by Consortium f. Elektrochemische Industrie [20]. It was further developed and used industrially by Wacker Chemie in Burghausen. Until 1965, almost all vinyl acetate was produced by the acetylene gas-phase process. Only two smaller plants used the ethylidene diacetate process [21]. Zinc salts on activated charcoal have proved to be effective catalysts. The development of suitable types of activated charcoal has improved the process [22].

Most of the industrial development work was concerned with carrying out the reaction. In the shaft furnaces used initially as reactors, controlling the heat of reaction was difficult. An occasional runaway of the reaction led to baking of the catalyst. Exothermic autodecomposition of the acetylene could not always be avoided. For better heat removal, other types of reactor employing a cooling medium were used. At Hoechst, Fischer furnaces were initially used, and at Wacker-Chemie tube furnaces.

As far as is known, all producers using the solid bed catalysts have started to use tube reactors because of the defined gas flow, the easier charging and discharging of the catalyst, and the good temperature control. Only at Kurashiki in Japan, Du Pont in the United States, and in some plants in the former Soviet Union have fluidized-bed reactors been used. Solid bed and fluidized bed processes are considered of equal value.

Process Description. The modes of operation of individual producers no longer differ significantly [23]. The process used by Hoechst until 1975 is described as an example (Fig. 1). Process data are given later in this section.

The circulated acetylene is preheated at the exit of the reactor in a countercurrent, and is then mixed with acetic acid vapor. The circulating gas can also be fed directly through the

Figure 1. Acetylene gas phase process for vinyl acetate production
a) Acetic acid evaporator; b) Reactor; c) Heat transfer oil, cooling loop; d) Quenching tower; e) Recycle gas blower; f) Liquid ring pump; g) Washing column; h) Regenerating column; i) Lightends column; j) Pure vinyl acetate column; k) Crotonaldehyde column; l) Acetic acid column; m) Residue column; n) Degassing column; o) Acetaldehyde column; p) Acetone column; q) Water removal

acetic acid evaporator (a). The gas, heated to the reaction temperature, enters the tube reactor (b).

The heat of reaction is removed by heat transfer oil in the cooling loop (c).

The mixture leaving the reactor is cooled in stages. The last cooling stage takes place in the quenching tower (d). In this packed column, the gas mixture is cooled to 0 °C. The condensate itself is used for cooling. It is circulated from the bottom to the top of the quenching tower via a brine – cooled condenser. The liquid product stream is removed; excess acetylene is recycled via a circulating gas blower (e).

The crude vinyl acetate produced at the bottom of the quenching tower is distilled giving acetic acid, which is recycled, and pure vinyl acetate. Some 90 % of the circulating gas is acetylene; the remainder is CO_2, CO, and methane formed from thermal decomposition, acetaldehyde, N_2, and other inert substances. To prevent enrichment of the impurities in the circulating gas, a small portion is removed behind the quenching tower (d) and then purified.

The acetylene from the gas stream, which has been brought to ca. 100 kPa overpressure by means of a liquid ring pump (f), is extensively absorbed in a washing column (g) containing brine-cooled vinyl acetate. The inert substances are led as waste-gas to flare. The sump product from (g) is freed from dissolved acetylene in a regeneration column (h) by boiling. The acetylene is recycled. The crude vinyl acetate formed in the bottom of the quenching tower (d) contains ca. 62 – 63 wt % vinyl acetate and 30 –35 % acetic acid. It also contains dissolved acetylene, acetaldehyde, crotonaldehyde, acetone, methyl acetate, ethylidene diacetate, and acetic anhydride.

In the lightends column (i) acetaldehyde, acetone, methyl acetate, dissolved acetylene, some vinyl acetate, and water (originating from the starting materials) are first distilled overhead. The sump product is fractionated in distillation columns (j – m). Pure vinyl acetate is removed as the top product of the column (j). In (k) crotonaldehyde distills at the head as an azeotrope after addition of water. The bottom of the acetic acid

column (l) also contains, besides acetic acid, the high-boiling ethylidene diacetate and acetic anhydride (unless they have already been hydrolyzed in the crotonaldehyde column), and very small quantities of polymers. Column (m) is operated under vacuum, and to some extent batchwise; the residual acetic acid distills so extensively that the liquid sump product which remains can subsequently be incinerated. The distillate from the lightends column (i) contains mainly acetaldehyde, acetone, methyl acetate, vinyl acetate, and water. It is purified in distillation columns (o – q).

Stabilizers. To avoid polymerization during the distillative work-up of the crude vinyl acetate, polymerization inhibitors are added. The preferred stabilizer is hydroquinone. Copper resinate, phenothiazine, or methylene blue are also used.

Materials and Environmental Aspects. The plant is made from mild steel in the hot area of the reaction section and in places where no liquid acetic acid is present. These areas include the reactor, the gas – gas heat exchanger, and the circulating gas blower. For the distillation section and the equipment in the reaction section which comes into contact with liquid product, stainless steel 316 L is used. The process has almost no polluting waste streams. All gaseous or liquid byproducts (high-boiling, crotonaldehyde, and acetone – methyl acetate fractions) can be incinerated. Waste circulating gas is passed to the excess gas burner.

Process Data. The catalyst consists of zinc acetate on activated charcoal (particle size 3 – 4 mm) as the carrier material. The zinc content is 10 – 15 wt %. The catalyst is produced by dipping. As the activated charcoal can contain traces of copper, small quantities of other components are added to the catalyst to prevent the formation of cuprene, which can block the tubes.

The operating time is ca. 5000 – 7000 h, depending on the type of activated charcoal used. It also depends on the purity of the acetylene and the circulating acetic acid. When using acetylene produced from carbide, the type of carbide is important. Because of the varying contents of phosphorus hydrides, hydrogen sulfide, arsine, and ammonia in the acetylene, it sometimes has to be further purified before being used in vinyl acetate production. This involves several steps.

Acetylene produced from petrochemicals does not contain these components. The decrease in catalyst activity is caused to a small extent by migration of zinc acetate out of the catalyst, but to a greater extent by formation of byproducts or by foreign components, which either act as catalyst poisons or adhere to the catalyst surface and pores [24], [25]. Vinyl acetate itself does not appear to contribute to the deactivation of the catalyst under the reaction conditions.

The space – time yield for the vinyl acetate is normally 60 – 70 g per liter catalyst per hour.

The reaction temperature is 160 – 170 °C, depending on the type of activated charcoal used as catalyst, but increases to 205 – 210 °C as the catalyst activity decreases. At the elevated temperature in the reactor, more byproducts are formed.

The pressure can increase a little during the operating time of a catalyst charge. This is caused by a slight increase in the flow resistance of the catalyst. The maximum pressure is ca. 40 kPa overpressure. Plants are protected against overpressures greater than 40 – 50 kPa because acetylene can undergo exothermic autodecomposition at high pressures and temperatures:

$$CH{\equiv}CH \rightarrow H_2 + 2\,C \quad \Delta H = -229.4\ \text{kJ/mol}$$

The acetylene pipes leading to the plant therefore contain barriers which inhibit the acetylene autodecomposition. The plants are also provided with equipment for automatic flushing with inert gas. The molar ratio acetic acid : acetylene is normally between ca. 1 : 4 and 1 : 4.5. The load per m^3 catalyst is ca. 135 m^3 (STP) recycle gas per hour and 76 kg acetic acid per hour. The recycle gas consists of ca. 90 % acetylene. Acetylene conversion is ca. 15 % and acetic acid conversion ca. 55 %. The yields based on acetic acid can reach 99 %, or 98 % based on acetylene, if the acetaldehyde formed (2 – 3 kg per 100 kg vinyl acetate) is included in the yield.

2.2.2. Ethylidene Diacetate Process

$$CH_3CHO + (CH_3CO)_2O \rightarrow CH_3CH(OCOCH_3)_2$$

$$CH_3CH(OCOCH_3)_2 \rightarrow CH_3CO_2CH{=}CH_2 + CH_3CO_2H$$

The process was developed by Celanese Corporation of America [26] and was operated industrially in the United States from 1953 to 1970,

and then replaced by the ethylene gas-phase process. A small plant (Celmex) operated in Mexico until 1991. Acetic anhydride is converted to ethylidene diacetate with acetaldehyde in the liquid phase using catalysts such as iron(III) chloride. The ethylidene diacetate is then cleaved thermally to vinyl acetate and acetic acid, using catalysts such as toluenesulfonic acid. Some of the ethylidene diacetate is converted back to acetic anhydride and acetaldehyde.

2.2.3. Reaction of Acetic Acid with Ethylene and Oxygen

Liquid-Phase Process. The formation of vinyl acetate from ethylene and acetic acid in the presence of palladium chloride and alkali acetate in glacial acetic acid was first described by MOISEEW [27]:

$$C_2H_4 + PdCl_2 + CH_3CO_2H \rightarrow CH_3CO_2CH{=}CH_2 + 2\,HCl + Pd$$

Addition of benzoquinone to the reaction mixture was said to reoxidize the palladium to palladium chloride. The reaction corresponds to the Wacker – Hoechst process, in which acetaldehyde is obtained from ethylene and water in the presence of palladium chloride:

$$C_2H_4 + PdCl_2 + H_2O \rightarrow CH_3CHO + Pd + 2\,HCl$$

The palladium formed is reoxidized to Pd^{2+} with copper(II) chloride. The copper(I) chloride formed is reoxidized with oxygen (→ Acetaldehyde, Chap. 4.3.1.). Production of vinyl acetate by a similar route has been widely investigated [28–30]. Corresponding production plants were commissioned by ICI in England, Celanese in the United States, and Tokuyama Petrochemical in Japan [31], but later shut down. Now only the ethylene gas-phase process uses ethylene as the starting material (see below).

In the liquid-phase process, a recycle ethylene gas stream is passed through a reaction solution containing acetic acid, water, high-boiling byproducts analogous to those of the acetaldehyde process, $PdCl_2$, and $CuCl_2$. Oxygen is passed into the reaction solution at the same time to reoxidize the palladium and the CuCl. The reaction and regeneration of the catalyst take place in one step:

$$CH_2{=}CH_2 + CH_3CO_2H + PdCl_2 \rightarrow CH_3CO_2CH{=}CH_2 + 2\,HCl + Pd$$

$$Pd + 2\,CuCl_2 \rightarrow PdCl_2 + 2\,CuCl$$

$$2\,CuCl + 2\,HCl + 1/2\,O_2 \rightarrow 2\,CuCl_2 + H_2O$$

Water is formed in the reoxidation of CuCl; part of the vinyl acetate formed is hydrolyzed to acetaldehyde and acetic acid. Part of the acetaldehyde is also formed directly from ethylene, as in the acetaldehyde process.

A certain ratio of palladium ions to copper ions and of copper ions to chloride ions is necessary for reoxidation of the palladium. Chlorine, which is lost through formation of chlorinated byproducts, is replaced by hydrochloric acid. To maintain the necessary quantity of chloride ions in solution, alkali metal chloride must be added. A typical reaction solution contains ca. 30 – 50 mg/L palladium ions and 3 – 6 g/L copper ions.

Byproducts include CO_2, formic acid, oxalic acid, oxalic acid esters, chlorinated compounds, and butenes. The pressure is 3 – 4 MPa, and the reaction temperature 110 – 130 °C. The ratio of acetaldehyde to vinyl acetate can be controlled by adjusting the water concentration and the residence time [32].

Gas-Phase Reaction. The process was developed to an industrial scale only slightly later than the ethylene liquid-phase process, and has been used in industry since 1968. Currently, 80 % of world vinyl acetate capacity uses the ethylene gas-phase process. There are two variants: one developed by National Distillers Products (United States) [49], and the other independently by Bayer in cooperation with Knapsack and Hoechst (Germany) [33–35]. Most plants employ the Bayer – Hoechst variant, of which there are several versions. The original process has been further developed by various operators.

In the ethylene gas-phase process, ethylene reacts exothermically with acetic acid and oxygen on solid bed catalysts, giving vinyl acetate and water:

$$CH_2{=}CH_2 + CH_3CO_2H + 1/2\,O_2 \rightarrow CH_3CO_2CH{=}CH_2 + H_2O$$

$\Delta H = -178$ kJ/mol

All catalysts used in industry contain palladium and alkali metal salts on carrier materials, e.g., silicic acid, aluminum oxide, lithium spinel, or activated charcoal. Additional activators can include gold, rhodium, platinum, and cadmium.

The reaction mechanism is assumed to involve either pure metal catalysis [36] or a reaction sequence according to the following equations:

$$CH_2{=}CH_2 + Pd(CH_3CO_2)_2 \rightarrow Pd + CH_3CO_2CH{=}CH_2 + CH_3CO_2H$$

$$Pd + 1/2\,O_2 + 2\,CH_3CO_2H \rightarrow Pd(CH_3CO_2)_2 + H_2O$$

The finely divided palladium on the catalyst is thought to be oxidized to divalent palladium. For reoxidation of the palladium, a redox reaction analogous to the liquid-phase process is assumed. Copper, manganese, and iron are cited as redox elements [37].

In the process, which operates above 140 °C and at overpressure 0.5 – 1.2 MPa, practically no acetaldehyde is formed, even if the acetic acid used as starting material contains water. Byproducts are water, CO_2 and small quantities of ethyl acetate, ethylidene diacetate, and glycol acetates.

Process Description: Reaction Section (Fig. 2). The recycle gas stream, which consists mainly of ethylene, is saturated with acetic acid in the evaporator (a) and is then heated to the reaction temperature. The gas stream is then mixed with oxygen in a special unit.

The allowed oxygen concentration is determined by the flammability limits of the ethylene – oxygen mixture. The flammability limit depends on temperature, pressure, and composition. It is shifted by additional components, such as acetic acid, nitrogen, and argon, which are brought in with the oxygen, or by CO_2. In general, the oxygen concentration at the entry to the reactor is ≤ 8 vol %, based on the acetic-acid-free mixture. It is essential to avoid gas mixtures capable of igniting; great care is taken in mixing in oxygen and measuring the oxygen concentration. If the oxygen stream is switched off, the inlet line must be flushed with nitrogen immediately to avoid back-diffusion of the circulating gas. The mixing chamber is usually installed behind concrete walls. The heat of reaction is removed in the form of steam via (c) from the tube reactor (b) by evaporative cooling in the shell side of the reactor.

The reaction temperature is adjusted by the pressure of the boiling water. The steam formed can be used within the plant itself in the work-up section. The heat of reaction is ca. 250 kJ/mol based on vinyl acetate, because of the simultaneous formation of CO_2. Pressurized water in a circulation loop is used for cooling in some plants.

Ethylene conversion is 8 – 10 %, and that of acetic acid 15 – 35 %. Oxygen conversion can be up to 90 %. As small quantities of alkali metal salt on the catalyst migrate under the reaction conditions, traces of alkali metal salt are mixed with the gas at the entry to the reactor [38].

The gas mixture leaving the reactor is first cooled in (d) in countercurrent with the cold recycle gas, which is thus warmed. There is virtually no condensation of the acetic acid, vinyl acetate, or water. The dew point is generally not reached. The gas mixture is then led into the predehydration column (l) and then cooled to about room temperature in (e). The liquid product consists of an acetic-acid-free mixture of vinyl acetate and water. The mixture is separated in a phase separator (m) into an aqueous phase, which is removed, and an organic vinyl acetate phase, which is recycled to the head of the predehydration column.

Between 40 and 50 % of the water formed in the reaction is removed in this way without the need to supply extra energy; this quantity of water does not need to be removed in the subsequent distillation of the crude vinyl acetate. Most of the energy consumed in the distillation is used for water removal. Crude vinyl acetate, which is low in water, collects in the sump of the predehydration column. Older plants do not have this column [39]. The noncondensed vinyl acetate fraction is washed out of the circulating gas with acetic acid in column (f) [40]. The remaining gas is recycled via compressor (g), after addition of fresh ethylene.

To remove the CO_2 formed in the reaction, a partial stream of recycle gas is first washed with water in column (h) to remove the remaining acetic acid. The CO_2 is then absorbed with potash solution in column (i). The potash solution is regenerated by depressurizing to normal

pressure and boiling (j). Depending on the quantity of CO_2 formed in the reactor, the desired CO_2 content of the circulating gas can be adjusted by altering the quantity of circulating gas present in the circulating gas wash, and the degree of absorption in the potash wash. The CO_2 concentration is generally 10 – 30 vol % [41], [42]. It is also possible to perform water and CO_2 washes in the main gas stream [43].

Figure 3. Ethylene gas-phase process for vinyl acetate production; work-up of crude vinyl acetate
a) Azeotrope column; b) Wastewater column; c) Drying/lightends column; d) Pure vinyl acetate column

To remove inert gases (nitrogen, argon) mainly brought in with the oxygen, a small quantity of waste-gas is removed before the CO_2 absorption column (i) and then incinerated. In some plants, part of the ethylene contained in this waste-gas is recovered by additional purification to reduce ethylene loss.

The liquid products formed, i.e., the condensate from the sump of the predehydration column (l) and the sump of the circulating gas wash, are depressurized to almost normal pressure and drained off into a collector for crude vinyl acetate (k). The circulating gas portions dissolved under the pressure of the circulating gas system are degassed and recycled to the circulating gas system after compression.

Process Description: Distillation Section. Distillative work-up of the liquid products to give acetic acid (which is recycled) and pure vinyl acetate is carried out in various ways, depending on the location of the plant and on the relative importance of energy consumption and investment costs. Besides the systems shown in Figures 3 and 4, combinations of both versions are used.

The liquid products contain 20 – 40 wt % vinyl acetate and ca. 6 – 10 vol % water. The rest consists of acetic acid and small quantities of byproducts, e.g., ethylidene diacetate and ethyl acetate. To work up the liquid products (Fig. 3) a vinyl acetate – water mixture can be distilled at the head in a first distillation (a). This mixture separates into two phases. The dissolved vinyl acetate is distilled from the water phase in wastewater column (b). The remaining water is wastewater. The organic vinyl acetate phase

is freed as the top product in a second distillation (c) from dissolved water, other volatile products, and acetaldehyde, formed by vinyl acetate hydrolysis. The sump product is dry vinyl acetate, which is distilled in a third distillation column (d) to give pure vinyl acetate as the top product.

Figure 4. Ethylene gas-phase process for vinyl acetate production; variant for work-up of crude vinyl acetate
a) Dehydration column; b) Pure vinyl acetate column; c) Wastewater column

To remove polymers, a small partial stream is removed from the sump of the third distillation column and fed back to the first column. Thus all nonvolatiles and polymers produced in the distillative work-up are contained in the sump of the first column, together with the recycled acetic acid. To remove the polymers and nonvolatiles, a partial stream is removed from the acetic acid evaporator in the reaction section of the plant. From this, the acetic acid for recycling is distilled so that the residue, which is still flowable, can be incinerated.

The small quantities of ethyl acetate formed are removed through a side exit in the first column (a) as a mixture with acetic acid, water, and vinyl acetate [44].

If an additional column is used for the work-up, only the dissolved water is distilled over in the second distillation, in the third the light ends, and in the fourth the pure vinyl acetate [45].

In another version (Fig. 4) the water contained in the crude vinyl acetate is removed as an azeotrope with the vinyl acetate together with volatile products, e.g., acetaldehyde, in a first distillation column (a), which operates at increased pressure. The dry bottom product, which contains vinyl acetate, acetic acid, polymers, and nonvolatiles, is fractionated in a second column (b) into pure vinyl acetate as the top product, and acetic acid and nonvolatiles. The last two are recycled. Ethyl acetate is removed through a side exit in the second distillation column as a mixture with acetic acid and vinyl acetate [46], [47].

To avoid polymer formation during the distillative workup of the crude mixture, polymerization inhibitors, e.g., hydroquinone, benzoquinone, or *tert*-butylcatechol, must be added. Passing in oxygen-containing gases is also said to inhibit polymerization [48].

Process Data. The catalysts used always contain palladium as the metal or a salt, alkali metal salts, and additional activators, e.g., metallic gold or alkali acetoaurate, cadmium acetate, or noble metals of the platinum group. Silicic acid of various structures, aluminum oxide, spinel, or activated charcoal are mainly used as the carrier material [49–54], [55].

The space–time yield for vinyl acetate is $200\,g\,L^{-1}h^{-1}$, in older plants up to more than $1000\,g\,L^{-1}h^{-1}$, depending on the catalyst and the plant layout. The life time of the catalyst is ≤ 4 a.

The reaction pressure is 0.5–1.2 MPa overpressure. The space–time yield for vinyl acetate increases with the reaction pressure and with the oxygen concentration in the reaction gas. However, an increase in pressure shifts the flammability limits of ethylene–oxygen to lower oxygen concentrations, reducing the quantity of oxygen available, and consequently the quantity of vinyl acetate formed, so pressure limits are set; higher pressures also raise equipment costs.

The reaction temperature is generally $> 140\,°C$. It increases to $> 180\,°C$ towards the end of the catalyst life. A lower reaction temperature results in the formation of less CO_2, but then the heat produced in the reactor can no longer be used in the plant.

The gas loading of the catalyst is $2-4\,m^3$ (STP) per liter catalyst per hour. The gas mixture contains 10–20 mol % acetic acid, 10–30 % CO_2, and ca. 50 % ethylene. The maximum oxygen content is ca. 1.5 % below the flammability limit, which varies with the composition of the gas mixture and the reaction conditions. The nitrogen and argon contents are adjusted according

to the quantity of waste gas. They are generally ca. 10 %, but depend on the purity of the oxygen used.

For old plants, energy consumption is ca. 3 t of heating steam per tonne of vinyl acetate produced. As a result of process improvements, modern plants have a heating steam consumption of 1.2 t per tonne of vinyl acetate.

The yields are up to 99 % based on acetic acid, and up to 94 % based on ethylene, if the acetaldehyde, formed in small quantities by hydrolysis of vinyl acetate during the distillative work-up, is included in the yield.

The process has not yet posed any environmental problems. Volatile and nonvolatile liquid products are incinerated. The water produced in the reaction can contain traces of acetic acid formed by hydrolysis of vinyl acetate in the wastewater column. It is subjected to biological wastewater treatment. To remove inert gases brought in with the oxygen, some of the waste-gas containing nitrogen and argon is burned after partial recovery of the ethylene it contains. There are small quantities of residual ethylene in the CO_2, formed in the regeneration column of the potash absorber. Removal of ethylene, e.g., by subsequent catalytic incineration, is now necessary in Germany because of more stringent regulations. In addition, special measures are required for waste-gas incineration.

Plants are generally made from stainless steel 316 L, apart from the potash washer, which is made from normal steel or stainless steel 321.

Proposals for Process Improvement. Since the first plants for the ethylene gas-phase process were commissioned, numerous suggestions have been made for improving the process; some of these are now being introduced industrially. Proposals regarding the catalyst include: simplification of production methods [56]; activity improvement (increase in vinyl acetate space – time yield [57–60], [55], [61]; improvement in selectivity (less CO_2 formation) [62], [63]; increase in life span [64–66]; reduction in flow resistance in the reactor (form of carrier material) [67]; better utilization of the noble metal content (distribution on the carrier) [68]; regeneration of spent catalysts [69–74].

Proposals regarding the mode of operation include: increasing the vinyl acetate space – time yield by raising the oxygen concentration in the gas at the entry to the reactor by adding desensitizers [75]; facilitating separation of ethyl acetate from vinyl acetate [76–79]; increasing the selectivity of the reaction by adding other components to the reaction gas [80]; carrying out the reaction on a fluidized bed [81]; lowering the energy consumption, e.g., by making use of the heat of condensation of the gas coming out of the reactor for removal of the water formed (see Section 2.2) [39]; simplified work-up of the polymer-containing residue [82].

2.2.4. Reaction of Methyl Acetate with CO and H_2.

Several companies have attempted to develop a reaction which, in principle, has been known for a long time. It involves the conversion of methanol, acetic anhydride, dimethyl ether, or preferably methyl acetate to ethylidene diacetate with carbon monoxide and hydrogen [83–95], [96–98]:

$$2\,CH_3CO_2CH_3 + 2\,CO + H_2 \rightarrow (CH_3CO_2)_2CHCH_3 + CH_3CO_2H$$

The reaction takes place in the liquid phase at ca. 7 MPa and ca. 150 °C. Rhodium salts together with methyl iodide and amines can be used as catalyst. The ethylidene diacetate formed can be cleaved to vinyl acetate and acetic acid, using the process previously employed by Celanese (see Section 2.2). As the acetic acid formed in the process can be reesterified to methyl acetate using methanol, the process essentially involves production of vinyl acetate from methanol and synthesis gas:

$$2\,CH_3CO_2CH_3 + 2\,CO + H_2 \rightarrow (CH_3CO_2)_2CHCH_3 + CH_3CO_2H$$

$$(CH_3CO_2)_2CHCH_3 \rightarrow CH_3CO_2CH{=}CH_2 + CH_3CO_2H$$

$$2\,CH_3OH + 2\,CH_3CO_2H \rightarrow 2\,CH_3CO_2CH_3 + 2\,H_2O$$

Dimethyl ether can also be used to prepare methyl acetate:

$$CH_3OCH_3 + CO \rightarrow CH_3CO_2CH_3$$

It is said to be possible to produce dimethyl ether by partial oxidation of natural gas:

$$2\,CH_4 + O_2 \rightarrow CH_3OCH_3 + H_2O$$

Byproducts are formed in all the steps; recovering them in pure form is expensive [99–102].

The process has not yet been used in industry. It could become more important, depending on the further development of raw material prices.

2.3. Quality Specifications, Analysis,Storage, Transport, and Toxicology

Quality. The specifications of individual producers often differ only slightly with regard to the content of impurities. One specification requires: vinyl acetate ≥ 99.9 wt %, acid (as acetic acid) ≤ 0.005 wt %; carbonyl (as acetaldehyde) ≤ 0.02 wt %, water ≤ 0.04 wt %; distillation range 95 % at 72 – 73 °C within 0.5 °C; peroxide free; polymer free; capacity for polymerization (see Section 2.4)

Analysis. The following methods are used for quality testing:

Carbonyl groups: titration of the hydrochloric acid formed after conversion to the oxime using hydroxylamine hydrochloride solution
Water content: titration with Karl-Fischer solution
Acid content: neutral to litmus
Peroxide: test with potassium iodide solution
Polymer content: mixtures with petroleum ether must not produce turbidity or precipitation of solids
Polymerization test: carried out differently by individual producers; the time taken for the onset of polymerization following the addition of a defined quantity of dibenzoyl peroxide and warming to a defined temperature

Storage. As a flammable liquid, vinyl acetate is assigned to VbF, group A, class 1, and ignition group T 2 according to VDE 0165. It can be stored in steel, aluminum, or stainless steel containers under nitrogen. It is not necessary to add stabilizers at lower temperatures. If the vinyl acetate is to be warmed, stabilizers, such as hydroquinone, hydroquinone monomethyl ether, or diphenylamine are added. The quantity of stabilizer used is small, e.g., 3 – 20 ppm hydroquinone, so that it does not generally need to be removed during the later polymerization.

Table 1. World vinyl acetate capacities

Country	Process	Capacity, 10^3 t/a
United States	Ethylene Bayer – Hoechst and National Distillers	1429
Canada	Ethylene Bayer – Hoechst	54
Mexico	Ethylene Bayer – Hoechst	100
South America	Acetylene, Ethylene National Distillers	100
Australia	Ethylene Bayer – Hoechst	14
Germany	Ethylene Bayer – Hoechst	280
France	Acetylene	150
Spain	Ethylene Bayer – Hoechst, Acetylene	100
United Kingdom	Ethylene Bayer – Hoechst	100
Italy	Acetylene	60
Eastern Europe	Ethylene Bayer – Hoechst, Acetylene	288
Japan	Ethylene Bayer – Hoechst and National Distillers, Acetylene	612
Near East	Ethylene Bayer – Hoechst and National Distillers	90
India	Ethylene Bayer – Hoechst	50
Korea	Ethylene Bayer – Hoechst	150
Taiwan	Ethylene Bayer – Hoechst	100
China	Ethylene Bayer-Hoechst, Acetylene	224

Transport. Vinyl acetate is transported in practically all quantities: small containers, drums, tankers, tank cars, and ships. Stabilizers are usually added for transportation.

2.4. Use, Economic Importance

Vinyl acetate is used mainly for the production of polymers and copolymers, e.g., for paints (mainly dispersions), adhesives, textile and paper processing, chewing gum [→ Poly(Vinyl Esters), and for the production of poly(vinyl alcohol) (→ Paints and Coatings, Chap. 2.4.5.) and polyvinylbutyral (→ Paints and Coatings, Chap. 2.4.6.).

Vinyl acetate – ethylene copolymers (→ Poly(Vinyl Esters), Chap. 6.) are processed to give resins, paints (→ Paints and Coatings, Chap. 2.4.4.), and sheeting. Floor coverings and gramophone records are made from vinyl acetate – vinyl chloride copolymers. Vinyl acetate is also used in small quantities as a comonomer in polyacrylic fiber production.

Uses differ according to the region. In Japan, ca. 70 % of vinyl acetate is used in the production of poly(vinyl alcohol), while in the United States and Europe more than half is processed to give poly(vinyl acetate).

The total capacity for vinyl acetate production was $< 10^6$ t/a in 1965. In 1994 it was ca. 3.8×10^6 t/a. The rapid increase has been promoted significantly by the development of the ethylene gas-phase process. After ethylene had become one of the cheapest raw materials in the chemical industry, it was obvious that vinyl acetate should be produced from ethylene instead of acetylene. The vinyl acetate capacities of individual countries are listed in Table 1.

A plant with a capacity of 150 000 t/y is to be commissioned by Hoechst Celanese in South East Asia in 1997.

The economic optimum of individual process variants depends on location. Investment costs, material consumption (acetic acid, ethylene, acetylene), and energy consumption need to be compared. The weighting depends on the prices of energy and starting materials, and on official regulations specific to a particular country.

3. Vinyl Propionate

3.1. Properties

Physical Properties. Vinyl propionate [*105-38-4*], $CH_3-CH_2-COO-CH{=}CH_2$, M_r 100.1, is a clear, colorless, flammable liquid with an ester-like odor; *bp* 95 °C; d_4^{20} 0.917; n_D^{20} 1.404; solidification point – 80 °C;

viscosity 0.56 mPa · s at 20 °C; heat of combustion 26 922 kJ/kg; flashpoint according (Abel-Pensky) − 2 °C; specific heat (liquid) 2.12 kJ/kg; heat of evaporation 340 kJ/kg at *bp*; heat of polymerization 882 kJ/kg; vapor pressure 1.34 kPa at 0 °C, 6.45 kPa at 20 °C; explosion limits (vapor in air at 20 °C) 2.4 – 15.5 vol %; ignition temperature 360 °C; solubility in water 6.5 mL/L at 25 °C; solubility of water in vinyl propionate 8.5 mL/L at 25 °C.

Chemical Properties. Vinyl propionate closely resembles vinyl acetate in its chemical reactions and on polymerization. The greatest differences are the more difficult saponification and its activity as an internal plasticizer in copolymers.

3.2. Production

Vinyl propionate is produced on an industrial scale at BASF from acetylene and propionic acid in the gas phase. The catalyst is zinc propionate on activated charcoal.

Process Description (Fig. 5). The recycle gas from blower (a) with an overpressure of up to 40 kPa is driven through the heat exchangers (b), connected in series, where it is heated to ca. 160 °C. It consists of ca. 95 % acetylene together with inert gases and traces of vinyl propionate, propionic acid, and other reaction products. After the second heat exchanger, propionic acid vapor from (j) is mixed into the circulating gas, and the resulting gas mixture is heated to the reaction temperature in (c). Depending on the activity of the zinc propionate catalyst, the temperature in the contact reactors (d) is 160 – 190 °C. The heat of reaction is removed via a cooling medium (l) by means of evaporative cooling, and is used for steam production in (k). The reaction gases from the reactor outlet (d) are cooled to 80 °C in the heat exchangers (b). The reaction products and unreacted propionic acid are condensed by further cooling in (e), (b), and (f). The recycle gas is washed with propionic acid in (g) to remove vinyl propionate and acetaldehyde. A small quantity is removed via the waste – gas scrubber (h).

The crude mixture in (i) contains vinyl propionate, propionic acid, and, besides dissolved acetylene, small quantities of the byproducts acetaldehyde, crotonaldehyde, diethyl ketone, and propionic anhydride. The latter is hydrolyzed by addition of water. Diethyl ketone and crotonaldehyde are removed by special methods. Water, acetaldehyde, and acetylene are removed at the head of the lightends column.

The sump product is pumped to the purification column where pure vinyl propionate is obtained at the head. The sump product here is at a temperature of 150 °C, and contains propionic acid and higher-boiling products. The propionic acid is recovered 99.5 % pure in an acid recycling column.

The yield is over 98 % based on acetylene, and over 99 % based on propionic acid.

Quality. The following quality specifications are in use:

Purity (by GLC)	99.9 %
Ester content (from saponification number)	99.8 %
Water content	≤ 0.1 %
Acid content (calculated as propionic acid)	≤ 0.03 %
Color value	≤ 10 APHA

3.3. Use

Vinyl propionate is the starting material for the production of homopolymers and copolymers with common monomers, such as (meth)acrylic compounds, vinyl chloride, and other vinyl esters [→ Poly(Vinyl Esters), Chap. 6.]. The polymers are marketed as Propiofan brands (BASF).

4. Vinyl Esters of Higher Carboxylic Acids

Apart from vinyl acetate and vinyl propionate, the vinyl esters of only a few higher carboxylic acids are important (see Section 4.5.). The properties of polymers, e.g., poly(vinyl acetate), poly(vinyl chloride), polystyrene, and esters of poly(acrylic acid), are modified using these compounds as comonomers. With this type of modification paints hydrolyze less readily and absorb less moisture. The various production methods depend on the physical and chemical properties of the carboxylic acids to be vinylated.

Figure 5. Production of vinyl propionate (BASF)
a) Recycle gas blower; b) Heat exchangers; c) Superheater; d) Reactors; e) Condenser; f) Brine-cooled condenser; g) Recycle gas wash; h) Wastegas wash; i) Crude product receiver; j) Propionic acid evaporator; k) Cooling medium; l) Steam generator

4.1. Reaction with Acetylene in the Gas Phase

The reaction of a thermally stable higher carboxylic acid with acetylene in the gas phase is possible only if the *bp* is sufficiently low for it to be evaporated in an acetylene stream below the reaction temperature. Catalysts containing zinc or cadmium are suitable for the vinylation itself. The production process generally does not run as smoothly as that for vinyl acetate because the zinc salts of higher carboxylic acids, particularly the branched ones, are volatile and migrate from the catalyst more readily. This problem can be circumvented to a certain extent by modification of the catalyst [104].

4.2. Reaction with Ethylene and Oxygen

This process, analogous to that used for the production of vinyl acetate, has not been used industrially, although it is possible in principle [105]. As the molecular mass of the carboxylic acid increases, the quantity required per mole of vinyl ester also increases; the higher equipment expenditure for the ethylene process is no longer compensated for by the cheapness of ethylene compared with acetylene.

4.3. Transvinylation and Other Processes

The transvinylation of the corresponding carboxylic acid with vinyl acetate can be applied to almost all carboxylic acids.

$$CH_3CO_2CH{=}CH_2 + RCO_2H \rightleftharpoons RCO_2CH{=}CH_2 + CH_3CO_2H$$

Mercury, palladium, or silver salts are suitable catalysts [106–109]. Methods involving mercury salts are appropriate only for very special and expensive vinyl esters because of the associated work-up costs. The disadvantage of the transvinylation method lies in the fact that a large excess of vinyl acetate must be used. Also, working up the mixtures of vinyl acetate, acetic acid, the carboxylic acid, and its vinyl ester by distillation is not always straightforward. Vinyl esters of higher carboxylic acids have therefore been used for transvinylation instead of vinyl acetate.

In special cases, the reaction of a carboxylic anhydride with acetaldehyde or paraldehyde, and subsequent cleavage of the ethylidene dicarboxylate have proved successful [111]. This is analogous to the production of vinyl acetate from ethylidene diacetate. The dehydration of ethylene glycol monocarboxylates has also been proposed [112].

4.4. Reaction with Acetylene in the Liquid Phase (Wacker and Shell Processes)

The vinylation of thermally stable carboxylic acids can also be achieved by passing acetylene into a melt formed by heating the corresponding zinc carboxylate or a zinc carboxylate – carboxylic acid mixture to ca. 200 °C (Wacker and Shell processes). The reaction can also be carried out with acetylene – nitrogen mixtures at pressures of up to 2.5 MPa [112], [113]. Carboxylic anhydrides may also be present [114].

If the vinyl esters of the higher carboxylic acids are thermally unstable, the reaction with acetylene can be carried out in the presence of mercury catalysts, enabling the reaction temperature to be lowered to 60 – 70 °C.

With the Wacker and Shell processes, most vinyl esters of higher saturated carboxylic acids up to ca. C_{18} can be produced in the same plant. The Shell process is particularly suitable for vinylating branched higher carboxylic acids [115–117]. In the Wacker process, excess acetylene is passed through a melt consisting of the zinc salt of the corresponding carboxylic acid and the acid itself at ca. 200 – 220 °C. In the Shell process, the reaction mixture contains a high-boiling mineral oil fraction. The vinyl ester formed is carried out with the excess acetylene.

Process Description. A recycle acetylene gas stream is preheated and then passed into the vinylation reactor. This reactor can be a short bubble column, a normal stirred vessel, or a stirred vessel with a gas entrainment stirrer because of the low initial pressure of the acetylene. Trickle bed columns can also be used. The reactor is heated or cooled by a heat transfer oil in the jacket. It contains a melt of the carboxylic acid to be vinylated mixed with its zinc salt (Wacker) or a solution of the mixture in a solvent with $bp > 300$ °C, e.g., a mineral oil fraction with a low aromatic content (Shell). The reactor must be heated or cooled depending on the mode of operation and the nature of the carboxylic acid. At equilibrium, it is also possible to use adiabatic conditions. The reaction temperature is 200 –230 °C and depends to some extent on the carboxylic acid used. The vinyl ester formed and the unreacted carboxylic acid are stripped with the acetylene stream. The conditions described for the vinyl acetate process regarding removal of inert gases and safeguarding against acetylene decomposition also apply here (see Section 2.2). The crude mixture, which condenses on cooling, contains up to 90 wt % vinyl ester. The rest consists of unreacted carboxylic acid, carboxylic anhydride, and small quantities of other byproducts. For high-boiling vinyl esters, the distillative work-up of the crude mixture is carried out in vacuo. The vinyl ester is distilled after removal of volatile products, e.g., acetaldehyde and crotonaldehyde. The sump product of the ester distillation, consisting of acid, acid anhydride, and high-boiling products is recycled to the reactor. The carboxylic anhydride formed can first be hydrolyzed thermally to the carboxylic acid. The hydrolysis can also be effected in the reactor itself by addition of small quantities of water, e.g., brought in with the acetylene as steam. Addition of water is not necessary with α-branched carboxylic acids. To avoid enrichment of high-boiling products, a small partial stream of the reactor liquid is removed [118], [119].

A large number of vinyl esters have been produced by the methods described [120]. They are not quite as pure as vinyl acetate or vinyl propionate because the starting acids are less pure than acetic or propionic acid. Plants for the vinylation of higher carboxylic acids are operated by Wacker in Burghausen and by Shell in Moerdijk and Pernis (Holland). Only a few of these vinyl esters are still produced in large quantities. For data on other vinyl esters which have been produced in the past see [121].

4.5. Individual Vinyl Esters

Vinyl laurate [*2146-71-6*] (Wacker), M_r 226.3, colorless, oily liquid with a weak odor, purity 99.9 ± 0.1 %, acid number 1 ± 0.2 mg KOH/g, density at 20 °C 0.87 g/mL, solidification point 6.5 °C, refractive index $n_D^{20} = 1.437$, viscosity 2.617 mPa · s at 20 °C, heat of evaporation 146 kJ/kg at 5.5 kPa, vapor pressure 10 Pa at 50 °C, bp (550 Pa) 123 °C/(101.3 kPa) 254 °C, flashpoint 136 °C, ignition temperature 300 °C, lower explosion limit in air 0.5 % (calculated) [114], solubility in water < 1 g/L, solubility of water in the ester < 1 g/L. The ester is not stabilized during transport or storage. Biodegradabil-

ity, good; water hazard class WGK 2. Transport: not classed as hazardous goods.

Vinyl isononanoate (Wacker), M_r 184.3, colorless liquid with a weak, ester-like odor, acid content calculated as isononanoic acid $\leq 0.3\,\%$, carbonyl compounds calculated as acetaldehyde $\leq 0.1\,\%$, water content $\leq 0.05\,\%$, *bp* 145 °C at 100 kPa, 44 °C at 50 Pa, solidification point − 70 °C, density 0.872 g/mL at 20 °C, flashpoint 68 °C, ignition temperature 390 °C.

Vinyl Esters of Versatic 911, 10, and 1519 Acids (Shell). Versatic acids are produced by the Koch synthesis from olefins, carbon monoxide, and water (→ Carboxylic Acids, Aliphatic, Chap. 10.8.). 911 refers to mixtures with 9 – 11 carbons, 1519 to mixtures with 15 – 19 carbons. The vinyl ester of versatic acid 10 with general formula

is the most important. R^1, R^2, and R^3 are straight-chain alkyl groups, one of which is always a methyl group.

The vinyl ester of versatic 10 acid, $C_{12}H_{22}O_2$, M_r 198, is a colorless liquid with a slight, ester-like odor, color value ≤ 15 APHA.

Physical Data, Properties

Density at 20 °C	0.88 g/mL
Refractive index, n_D^{25}	1.435
Kinematic viscosity:	
at 20 °C	2.2 $mm^2\,s^{-1}$
at 40 °C	1.3 $mm^2\,s^{-1}$
Vapor pressure:	
at 30 °C	130 Pa
at 110 °C	4.25 kPa
at 210 °C	101 kPa
Solubility in water	< 0.1 wt %
Solubility of water in the ester	0.05 wt %
Acid number	≤ 1
Bromine number	80 g Br/100 g
Heat of evaporation	49 kJ/mol
Heat of polymerization	96.3 kJ/mol
Specific heat	1.97 J/g
Boiling range	133 – 136 °C at 13.3 kPa
Ignition temperature	309 °C
Solidification point	− 20 °C
TA-Luft class III	
VbF AIII	

Regulations governing hazardous substances: not hazardous as understood by these regulations. *Toxicology*

LD_{50}, oral, rat	> 8800 mg/kg
LD_{50}, dermal, rat	> 3500 mg/kg
LD_{50}, inhalation, rat, 4 h	> 2.6 mg/L
Ecology	
Fish toxicity	
(rainbow trout) LC_{50}, 96 h	14 mg/L
Daphnia toxicity LC_{50}, 48 h	110 mg/L
Green algae LC_{50}, 96 h	31 mg/L
Not readily biodegradable

1. Introduction

Vinyl ethers were first described by Wislicenus in 1878. He obtained ethyl vinyl ether by treating chloroacetal with sodium.

Vinyl ethers (CH_2=CH−O−R; R = alkyl, cycloalkyl, or aryl) may be regarded as derivatives of vinyl alcohol, the unstable enol form of acetaldehyde. Vinyl ethers with substituted vinyl groups are of laboratory interest only, and are not dealt with here. In the 1930s, alkyl vinyl ethers achieved industrial importance as the starting materials for polymers (→ Poly(Vinyl Ethers)), after they had been made readily accessible through the work of Reppe at I. G. Farbenindustrie, Ludwigshafen [1–4].

2. Properties

2.1. Physical Properties

The lower aliphatic vinyl ethers ($C_1 - C_4$) are colorless, combustible, mobile, volatile liquids with an ethereal odor. Methyl vinyl ether is gaseous under normal conditions, but can be liquefied under pressure (pressurized gas). Octadecyl vinyl ether, one of the higher vinyl ethers, is a low-melting solid of low volatility. Vinyl ethers are only slightly soluble in water, but readily miscible with most organic solvents (with the exception of glycol or glycerol). Some physical properties of industrially important vinyl ethers are given in Table 1.

2.2. Chemical Properties

Unlike the chemically very stable saturated ethers (→ Ethers, Aliphatic, Chap. 2.2.), vinyl ethers are extremely reactive substances because of the presence of the enol ether group. They can be readily polymerized in the presence of Friedel – Crafts catalysts, such as BF_3, $AlCl_3$, or $SnCl_4$ (→ Poly(Vinyl Ethers)). They are hydrolyzed by dilute aqueous acid at room temperature, to acetaldehyde and an alcohol [5, p. 391]. However, they are stable to alkalis, even hot aqueous caustic solutions.

Ethyl ethers are obtained by catalytic hydrogenation of vinyl ethers. In the presence of acid catalysts they react with alcohols to give acetals. Chlorine and bromine add to vinyl ethers giving 1,2-dihaloethyl ethers, but iodine causes polymerization, even in very small quantities. The reaction of halogens with vinyl ethers in

[e] = Vinyl-4-hydroxybutyl ether.

the presence of alcohols gives 2-haloacetals [5, pp. 391 –392]. Siggia's method of determination of vinyl ethers is based on this reaction [6]. Vinyl ethers undergo addition reactions with hydrogen halides giving 1-haloethyl ethers [4, pp. 92 – 93]. The reaction of vinyl ethers with *ortho* esters gives tetraacetals of dialdehydes. With dienes and 1,2-unsaturated aldehydes, vinyl ethers undergo a Diels – Alder reaction [5, pp. 392 – 395], [7, p. 227]. Vinyl ethers react with numerous other reagents, e.g., acetals, carboxylic acids, hydrogen cyanide, phosgene, carbon tetrachloride, ammonia, and amines [5, pp. 393 – 396].

3. Production

Methods for preparing vinyl ethers, e.g., reaction of alkali alkoxides with vinyl halides or dihalohydrocarbons [4, pp. 85 – 86], and transvinylation (transfer of a vinyl group from a vinyl ether or vinyl ester to another alcohol) [5, p. 371], [7, p. 207], [8, p. 508] have not achieved any importance for the production of vinyl ethers beyond laboratory scale.

The production of monovinyl ethers of diols can take place by transfer of a vinyl group from a diol divinyl ether to a free diol:

$$\begin{array}{l} \qquad\qquad\qquad CH_2{=}CH{-}(CH_2)_4{-}O{-}CH{=}CH_2 + \\ HO{-}(CH_2)_4{-}OH \rightleftharpoons 2\,CH_2{=}CH{-}O{-}(CH_2)_4{-}OH \end{array}$$

Butanediol-1,4-monovinyl ether

The equilibrium can be shifted in favor of monovinyl ether formation by excess diol. Compounds of the platinum group metals, in particular those of palladium, are used as catalysts [9].

Vinyloxycarboxylic acid esters (not accessible by Reppe vinylation) can be produced by vinyl group transfer from vinyl ethers to hydroxycarboxylic acid esters, using special palladium compounds as catalysts:

$$HO{-}CH_2{-}\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}COOCH_3 + CH_2{=}CH{-}O{-}i{-}C_4H_9$$

Methyl hydroxypivalate Isobutyl vinyl ether

$$\rightleftharpoons CH_2{=}CH{-}O{-}CH_2{-}\underset{\underset{CH_3}{|}}{\overset{\overset{CH_3}{|}}{C}}{-}COOCH_3 + i{-}C_4H_9{-}OH$$

Methyl vinyloxypivalate Isobutanol

Here also, the equilibrium can be shifted in favor of vinyloxycarboxylic acid ester formation by excess vinyl ether [10].

An industrial process for vinyl ether production involves the cleavage of acetals at 270 – 400 °C in the presence of palladium asbestos, thorium oxide, or manganese sulfate on aluminum oxide as catalyst:

$$CH_3{-}CH(OR)_2 \rightarrow CH_2{=}CH{-}O{-}R + R{-}OH$$

Ethyl, butyl, and isobutyl vinyl ethers have been produced industrially by this method (Union Carbide) [5, pp. 369 – 370], [7, p. 207], [8, p. 508]. Improved processes for vinyl ether production by acetal cleavage use special zeolites as catalysts (mordenite [11], borosilicate – iron silicate zeolites [12]), but these developments have not been exploited industrially.

Vinyl ethers are also obtained by elimination of hydrogen chloride from chloroethyl ethers using alkali [13]. For example, 2-chloroethyl vinyl ether used to be produced industrially from 2,2′-dichlorodiethyl ether by heating with solid NaOH (Union Carbide) [5, p. 371]:

$$\begin{array}{l} Cl{-}CH_2{-}CH_2{-}O{-}CH_2{-}CH_2{-}Cl + NaOH \rightarrow \\ \quad CH_2{=}CH{-}O{-}CH_2{-}CH_2{-}Cl + NaCl + H_2O \end{array}$$

In a catalytic oxidation process developed by ICI for the production of methyl vinyl ether, ethylene is reacted with methanol in the presence of palladium chloride complexes or palladium metal [14–16]. It is not known whether this process has been developed on an industrial scale:

$$CH_2{=}CH_2 + CH_3{-}OH \rightarrow CH_2{=}CH{-}O{-}CH_3 + H_2O$$

3.1. Reaction of Acetylene with Alcohols

The most important industrial method for the production of vinyl ethers is the reaction of acetylene with alcohols in the presence of strong alkalis in the liquid phase (Reppe vinylation) [3], [17]:

$$CH{\equiv}CH + R{-}OH \rightarrow CH_2{=}CH{-}O{-}R \quad \Delta H = -134\ \text{kJ/mol}$$

The strongly exothermic reaction is carried out in the presence of alkali alkoxide catalysts. The reaction proceeds particularly smoothly in the presence of the corresponding potassium compound [1], [4]. The vinylation temperature is generally 150 – 180 °C. With methanol, a vigorous reaction occurs at 120 °C.

3.2. Reaction Conditions

3.2.1. Introduction

The choice of operating pressure depends on the boiling point of the alcohol to be vinylated. Lower alcohols ($C_1 - C_4$) are vinylated under pressure, as their boiling points lie below the reaction temperature. Thus, methyl vinyl ether is produced at 1.6 MPa, ethyl vinyl ether at 1.5 MPa, and isobutyl vinyl ether at 0.8 MPa. The vinylation also succeeds at normal pressure if so much KOH is dissolved in the alcohol that the boiling point of the solution rises to the vinylation temperature or above. However, this method gives poor yields because of side reactions.

When working under pressure, the acetylene must be diluted with nitrogen for safety reasons [3] (→ Acetylene, Chap. 5.1.). The acetylene concentration must not exceed 55 % for methyl and ethyl vinyl ethers, and 75 % for isobutyl vinyl ether.

Higher alcohols can be vinylated at normal pressure as their boiling points are above the vinylation temperature. In this case, expenditure on equipment is significantly lower than in the pressure process. In the normal pressure process, octadecyl vinyl ether, vinyl ethers of fatty alcohol mixtures, and decalyl vinyl ether, for example, can be produced.

The vinylation of alcohols is also possible in the gas phase. A mixture of alcohol vapor and acetylene is passed over solid-bed catalysts, e.g., soda lime [4, p. 87], KOH on activated charcoal, or magnesium or calcium oxides [18], but such processes have not achieved any practical importance.

3.2.2. Dependence of Reaction Conditions on the Nature of the Alcohol

In the case of primary and secondary aliphatic alcohols, vinylation proceeds very smoothly, even for the highest homologues. Tertiary alcohols react less readily. Polyhydric alcohols, e.g., 1,4-butanediol, can be partially or fully vinylated (to monovinyl or divinyl ethers) depending on the reaction conditions chosen. Where the distance between the hydroxyl groups is small (e.g., with ethylene glycol) the cyclic acetal is formed from the monovinyl ether before the latter can react with the acetylene to give the divinyl ether. Alicyclic alcohols (e.g., cyclohexanol, 2-decalol (2-decahydronaphthol), terpene alcohols, tertiary aminoalcohols, and heterocyclic alcohols, such as hydroxyfuran, can also be vinylated. The vinylation of aminoalcohols with primary or secondary amino groups to give the corresponding vinyl ethers can best be carried out with so-called superbases as catalysts (DMSO with alkali hydroxide/alkoxide, preferably potassium compounds) [19]. Examples are 3-vinyloxy-1-propylamine, *N*-ethyl-2-vinyloxy-1-ethylamine, and 4-vinyloxypiperidine.

Phenols and naphthols react with acetylene less readily than aliphatic alcohols. The corresponding aryl vinyl ethers can be obtained only in the presence of a large quantity of potassium phenoxide and a good solvent for acetylene, e.g., *N*-methylpyrrolidone.

3.3. Process Description

In industry, vinyl ethers are produced in a vertical reaction tower (tube reactor). The alcohol, endowed with KOH, is charged at the top, while the gaseous mixture of acetylene and nitrogen is fed in from below. The acetylene not consumed in the reaction is led back into the reactor (recycling process) and supplemented by pure acetylene (fresh gas).

3.3.1. Production of Vinyl Ethers under Pressure

The pure acetylene is precompressed in the fresh gas compressor (Fig. 1, h) to the required operating pressure and then pumped into the pressure tower (c) from below by means of the circulating gas pump (g). At the same time, the alcohol, to which 2 – 3 % KOH has been added in the feed vessel (a), is continuously pumped from above toward (c), by pressure pump (b). The vinyl ether formed at 150 – 160 °C distills together with excess unreacted alcohol from the pressure tower (c), and is condensed out of the circulating gas stream in the condenser (e). The remaining circulating gas is led back to the circulating gas pump after removal of the waste gas

Figure 1. Production of vinyl ethers under pressure
a) Feed vessel; b) Pressure pump; c) Pressure tower; d) Sump exit; e) Condenser; f) Pressurized degasser; g) Circulating gas pump; h) Fresh gas compressor; i) Fores column; j) Purification column; k, l) Alcohol columns; m) Washing column; n) Drying column

by taking out inert components. The heat of reaction is removed by evaporation mainly of the vinyl ether – alcohol mixture and by a cooling coil in the pressure tower (c). A small proportion of the contents of the tower is removed at the lower end of the pressure tower via the drainage exit (d) to remove used catalyst and high-boiling side products from the reaction mixture.

The vinyl ether – alcohol mixture distilling from the pressure tower (c) is freed from dissolved acetylene in the pressure degasser (f) and from low-boiling fractions in the fores column (i). In the purification column (j) the vinyl ether is obtained at the distillation head by fractional distillation, and freed from alcohol residues in the washing column (m) by washing with a countercurrent of water. After drying with solid KOH in the drying tower (n) to remove residual moisture, the vinyl ether is sufficiently pure for further processing (polymerization).

Unreacted alcohol forming the sump in the purification column (j) is purified in two further distillation columns (k, l) and recycled to (a). The whole plant operates completely continuously.

The production of special vinyl ethers under pressure is carried out as a batch operation in stirred autoclaves (vinylation of cyclohexanol, butane-1,4-diol, diethylene glycol, etc.). The crude vinyl ethers produced are purified by vacuum distillation.

3.3.2. Pressure-free Production of Vinyl Ethers

Vinylation at normal pressure is carried out as a batch operation so that complete conversion of the alcohol is achieved and the purification of the reaction product is simplified.

The alcohol treated with 2 – 3 % KOH in the feed vessel (Fig. 2, a) is charged in batches to the top of the reaction tower (b). The pure acetylene is fed into the reaction tower from below by means of the circulating gas blower (d). Unreacted acetylene comes out of the top and passes back to the circulating gas blower (d) via the condenser (c). By removal of waste gas, the acetylene concentration in the gas circulation is held at ca. 90 % (the remainder is nitrogen). The reaction temperature is 170 – 180 °C. The heat of reaction is removed from the reaction tower (b) by means of a cooling coil.

After the reaction has finished (acetylene uptake falls to zero) nitrogen is blown through the crude vinyl ether to remove dissolved acetylene, and the vinyl ether is then passed into the stirred vessel (e) where it is purified by vacuum distillation using column (f) in a batch process.

4. Environmental Protection, Waste Disposal

To protect the environment, the residues and waste materials formed in the production of vinyl ethers must be disposed of according to the regulations. Gaseous waste products (process waste gas from the synthesis and displacement gas from the containers) are incinerated in an excess gas burner. Liquid waste and distillation residues are disposed of in an incineration plant for special wastes. Wastewater which is licensed for treatment is subjected to biological purification in a treatment plant. No environmental problems are encountered if disposal measures are carried out properly.

5. Quality Specifications

As precursors for polymer production, vinyl ethers are subject to high quality requirements. The specifications require a purity (vinyl ether content) >99.8 %, residual alcohol content <0.1 %, other side products <0.1 %, and water <0.01 %.

6. Chemical Analysis

Vinyl ethers are preferably analyzed by standard GLC methods. They may also be determined quantitatively by addition of iodine to the double bond of the vinyl group in the presence of methanol (Siggia's method) [6]. Absolutely dry vinyl ether (<0.01 water) does not attack freshly pressed sodium wire (no gas formation, no change in the lustrous metal surface within 1 h).

7. Storage and Transport

Vinyl ethers can be stored for only a limited period. They can be kept at 20 °C for several months if water and acids are excluded. They are stored in stainless or normal steel containers under dry nitrogen, which prevents the formation of combustible air – vapor mixtures. The exclusion of atmospheric oxygen inhibits the formation of peroxide in the stored product. Methyl vinyl ether (pressurized gas) is stored in pressurized containers.

High-boiling organic bases have proved to be useful stabilizers for inhibiting polymerization during transport of vinyl ethers, e.g., *N,N*-diethylaniline, or triethanolamine (soluble in the product). The quantity of stabilizer added is 0.05 – 0.1 %. The use of solid KOH in pellets as a stabilizer is limited to drums of up to 200 L.

Because vinyl ethers are readily flammable (see Table 1), the relevant safety instructions and explosion protection measures must be adhered to during production, storage, and transport. Dispatch regulations and hazard classes for transport are given in Table 2.

Table 2. Dispatch regulations for vinyl ethers: hazard classes

Vinyl ether	Rail, GGVE/ RID	Trucks, GGVS/ ADR	Ship, IMDG Code
Methyl	2,3 ct	2,3 ct	2, UN 1087
Ethyl	3,2 b	3,2 b	3,1 UN 1302
Propyl	3,3 b	3,3 b	3,1 UN 1993
Isobutyl	3,3 b	3,3 b	3,2 UN 1304
Octadecyl	none	none	none
Cyclohexyl	3,31 c	3,31 c	3,3 UN 1993
Butanediol-1,4-monovinyl ∗	3,32 c	3,32 c	none
Butanediol-1,4-divinyl	3,32 c	3,32 c	3,3 UN 1993
Diethylene glycol divinyl	3,32 c	3,32 c	

∗ = Vinyl-4-hydroxybutyl ether.

8. Use

Vinyl ethers are used principally for the production of homo- and copolymers, in the adhesives and varnish industries (→ Poly(Vinyl Ethers)). Vinyl ethers can also be used as chemical intermediates for the production of glutardialdehyde [7, p. 227], tetramethoxypropane [5, p. 392], γ-picoline [20], and 2-aminopyrimidine [21].

9. Toxicology

Investigations of toxicokinetics and metabolism have shown that, on inhalation, rapid resorption takes place, and that vinyl ethers are relatively stable and metabolized only slightly. They are mainly exhaled unchanged. Epoxidation of the vinyl group has not been described [22–25].

The acute toxicity of vinyl ethers is low. In rats the acute oral LD_{50} decreases with increasing chain length:

Methyl vinyl ether	4.900 mg/kg [22], [26]
Ethyl vinyl ether	8.160 mg/kg [27]
Butyl vinyl ether	10.300 mg/kg [28]
Isobutyl vinyl ether	13.100 mg/kg [29]

As LC_{50} indicates, the acute toxicity by inhalation in rats is also very low:

Methyl vinyl ether	150 mg/L	(4 h, rat) [26]
Ethyl vinyl ether	21.2 mg/L	(4 h, rat) [30]
Isobutyl vinyl ether	21.1 mg/L	(4 h, rat) [31]

The symptoms are characterized by the narcotic action of the vinyl ethers at high concentration. Compared with saturated alkyl ethers, the vinyl group reinforces the narcotic properties. Correspondingly, divinyl ether is a stronger narcotic than, for example, ethyl vinyl ether or diethyl ether.

On repeated inhalation (28-day test on rats) only slight systemic toxicity was observed at high concentration (25 000 ppm). With methyl vinyl ether there was an increase in the relative liver weight with no histopathological correlation and a local irritant effect on the mucosa of the nasal cavity in the form of atrophy of the olfactory epithelium. The no adverse effect concentration (NOAEC) was 1500 ppm (3.6 mg/L) for male rats and 3500 ppm (8.3 mg/L) for female rats. No other histopathological change was observed [22]. In experiments with dogs no changes in the liver, no electrocardiographic changes (dogs, monkeys), and no effect on blood pressure were found [32].

On contact with skin and with the mucous membranes of the eye, highly volatile vinyl ethers are not irritant, and those with low volatility slightly irritant [22], [29], [33], [34].

No data from skin sensitization experiments on animals are available. However, short-chain vinyl ethers are not expected to be hazardous because of their high volatility. In humans no cases of sensitization have been published, either in production of the compounds or for their earlier use as an inhaled narcotic.

In vitro investigations on genotoxicity are contradictory. On microorganisms (*Salmonella typhimurium*: Ames test) and with mammalian cells (HPRT test: [35]) vinyl ethers were not mutagenic, with or without metabolic activation. Chromosome aberrations could not be detected on somatic cells with isobutyl vinyl ether [36]. However, with ethyl vinyl ether and 2,2,2-trifluoroethyl vinyl ether possible indications of an increase in the sister chromatid exchange rate

(SCE test; [37]) have been described. In animal experiments no genotoxic activity was observed (micronucleus test; [22]).

No investigations of carcinogenicity and reproductive toxicity in animals have been reported.

From the use of ethyl vinyl ether as an inhaled narcotic in the 1950s, a number of effects on humans have been reported. In one out of 220 narcoses spasm of the larynx and flow of saliva occurred. In 12 of 220 cases there was generalized cramp and respiratory and cardiac arrest. Postnarcotic effects are: nausea/vomiting (26.7 %), reduction in circulation (4.1 %), excitation (1.6 %), and hypoxia (0.8 %). Liver function tests gave no indication of damage [38]. In another investigation indications of slight leukocytosis and slight myocardial depression were observed, but liver function tests showed no change [38].

1. Introduction

1.1. Definition [1]

Vitamins are essential, organic compounds which are either not synthesized in the human and animal organism or formed only in insufficient amounts. Therefore, they must be regularly consumed with the diet either as such or as a precursor (provitamin) that can be converted to the vitamin in the body. A typical representative of the provitamins is β-carotene, which is split into two molecules of vitamin A in the organism. The metabolic functions of vitamins are mainly catalytic or regulatory. In contrast to energy-providing nutrients, vitamins are required only in exceptionally small amounts. An inadequate supply of a vitamin leads to typical pathological deficiency symptoms which can be remedied by intake of the lacking vitamin.

Vitamins are classified not chemically but by their activity. The historical distinction between fat- and water-soluble vitamins has been retained to this day [2] because the solution properties are important not only for the occurrence, but also for the behavior of vitamins in the organism (resorption, transport, excretory pathways, and storage).

However, it is not the case that fat-soluble vitamins are stored much more effectively than water-soluble vitamins. The assumption that a deficiency of fat-soluble vitamins occurs after a much longer period than in the case of water-soluble vitamins (higher reserve capacity of liposoluble substances) is incorrect. In fact, the reserve capacity depends on the special prop-

erties of the particular vitamin, irrespective of differences in solubility [3].

In the case of vitamin B_{12}, for instance, the reserve capacity amounts to three to five years, but for thiamine it is only two weeks. Although vitamin K is fat-soluble, deficiency of this vitamin occurs shortly after the interruption of food intake and suppression of enteral synthesis. Consequently, the solubility properties of the individual vitamins only provide vague information about the occurrence and stimulation of absorption by lipids in the food and bile acids.

Table 1. Active forms and functions of vitamins

Vitamin	Active form	Function [4]
Vitamin A	(11-*Z*)-retinal	involvement in vision
Vitamin D		regulation of calcium and phosphate metabolism
Vitamin E		intracellular antioxidant
Vitamin K		biosynthesis of prothrombin
Vitamin B_1	thiamin pyrophosphate (TPP), thiamin triphosphate (TTP)	decarboxylation of α-oxo acids, transfer of aldehyde groups, phosphate donor
Vitamin B_2	flavinmononucleotide (FMN), flavinadenine dinucleotide (FAD), coenzymes of flavoproteins	hydrogen or electron transport in energy-releasing metabolism
Niacin	nicotinamide adenine dinucleotide (NAD), nicotinamide adenine dinucleotide phosphate (NADP)	hydrogen or electron transport
Pantothenic acid	coenzyme A (CoA)	transfer of acetyl groups
Vitamin B_6	pyridoxal-5-phosphate	transfer of amino groups
Biotin	biocytin	transfer of carboxyl groups
Folic acid	tetrahydrofolic acid	transfer of formyl groups
Vitamin B_{12}	coenzyme B_{12}	1,2-hydrogen shift
Vitamin C		involvement in hydroxylation, ultracellular antioxidant

On the basis of the above definition, thirteen compounds or groups of compounds have been classified as vitamins for humans (Table 1):

Fat-soluble vitamins
Vitamin A (retinols)
Vitamin D (calciferols)
Vitamin E (tocopherols, tocotrienols)
Vitamin K (phylloquinone)

Water-soluble vitamins
Vitamin B_1 (thiamin)
Vitamin B_2 (riboflavin)
Vitamin B_6 (pyridoxal group)
Vitamin B_{12} (cobalamins)
Vitamin C (L-ascorbic acid)
Pantothenic acid
Biotin
Folic acid
Niacin

Other compounds exist that are also important for the organism and cannot always be produced in sufficient quantities. Hence, an alimentary additional requirement can arise under certain conditions. These are known as pseudovitamins.

1.2. Substances with Vitamin-Like Character

In the past, many authors regarded the essential fatty acids ("vitamin F"), lipoic acid, ubiquinones, choline, myoinositol, "vitamin U" (*S*-methylmethionine), and some other substances and substance mixtures as vitamins. Some characteristics of these substances are listed in Table 2.

1.3. History

The term "vitamins" was introduced by Funk [5] in 1911. Searching for the causes of beriberi, a nervous disease often encountered in East Asia, Eijkman showed in 1896 [6] that polished rice caused this disease and that it could be cured by consumption of rice bran. In 1911, Funk isolated a substance in the form of water-soluble crystals from rice bran. This substance was responsible for curing beriberi and was named "beriberi vitamin".

The designation "vitamin" was accepted for all the essential nutritional factors discovered in the following period, although it was soon recognized that not all these substances are amines. According to a proposal made by Drummond [7] in 1920, the beriberi vitamin was designated vitamin B, the fat-soluble antixerophthalmia factor was named vitamin A, and the

Table 2. Compounds with vitamin or coenzyme character

Compound	Formula	Source/compound	Biological importance
Vitamin F (essential fatty acids)		plant oils fish oils	component of membranes
Lipoic acid		animal and plant cells	growth factor
Vitamin Q (ubiquinone)		animal and plant cells	factor in the redox system of the respiratory chain
Myoinositol		plant cells	nutrient for microorganisms, growth factor for yeasts and fungi
Vitamin U (*S*-methyl-methionine)		vegetables	"antipeptic ulcer factor"
Choline chloride		animal and plant cells	growth and metabolic factor, deficiency causes fatty liver, hypotensive
Taurine		oxidative degradation product of cysteine	conjugate formation with bile acids → fat resorption
Carnitine		animal and plant cells	growth factor for lower life forms, involvement in fat metabolism
Orotic acid (Vitamin B_{13})		yeasts, liver, milk	intermediate in pyrimidine metabolism, growth factor
Adenosine monophosphate (Vitamin B_8)		component of coenzymes (CoA, NAD^+, FAD), structural unit of ribonucleic acids	allosteric effector in the phosphofructo kinase and fructose diphosphatase reactions
Adenosine-3′,5′-monophosphate (cyclic AMP)		animal and plant cells	transfer of the effect of hormones and hormone-like substances

antiscurvy factor was named vitamin C. All the vitamins discovered later were included in this classification.

A survey of the discovery, isolation, and assignment of the chemical structure of the individual vitamins is presented in Table 3.

As mentioned above, the discovery of the vitamins was due to the fact that a deficiency can severely damage the organism. Therefore, the substances that should be regarded as vitamins are all known today. It is unlikely that new food constituents which fully correspond to the definition of vitamins with regard to their occurrence and action will be discovered.

Nevertheless, the "history of vitamins" has still not come to an end. A constantly increasing

Table 3. Discovery of the vitamins

Vitamin	First isolation	Discovery	Isolation	Structural elucidation
Vitamin A	fish liver oil	1909	1931	1931
Vitamin D	fish liver oil	1918	1932	1936
Vitamin E	wheat germ oil	1922	1936	1938
Vitamin K	alfalfa	1929	1939	1939
Vitamin B_1	rice	1897	1911	1936
Vitamin B_2	eggs	1920	1933	1935
Vitamin B_6	rice	1934	1938	1938
Vitamin B_{12}	liver	1926	1948	1956
Niacin	liver	1936	1935	1937
Folic acid	liver	1941	1941	1946
Panthothenic acid	liver	1931	1938	1040
Biotin	liver	1931	1935	1042
Vitamin C	lemons	1912	1928	1933

number of publications deal with the preventive effects of vitamins on vascular diseases and various types of cancer (see Section 1.6).

1.4. Determination of Requirement

According to the definition of the term vitamin, an inadequate supply of vitamins causes a certain deficiency (hypovitaminosis or avitaminosis).

In the case of avitaminosis, a minimum amount of vitamin is required to remedy these conditions. However, this amount does not correspond to the true requirement. No exact data can be given for this requirement because it varies from individual to individual and strongly depends on the physical condition of the particular person. In stress situations (e.g., illness, pregnancy, and physical exertion), the requirement is considerably higher. Even when in human experiments the selected group of persons is well balanced in this respect, substantial variations remain, which are mainly due to the difficulty of producing the same state of deficiency at the start of the investigation and in evaluating the often complex deficiency symptoms.

For this reason, it is meaningful to stipulate the "desirable supply" of a vitamin (recommended dietary intake = RDI or recommended dietary allowance = RDA) instead of the exact requirement. Experience shows that full health and productivity are observed at these levels of intake. RDA values are regularly issued by the U.S. Food and Nutrition Board, the U.K. Department of Health and Social Security, WHO, and by the German Society for Nutrition (DGE) [8]. A compilation issued in 1991 is listed in Table 4.

1.5. Application and Tolerance

Vitamins are used as single preparations or as multivitamin preparations in the treatment of hypovitaminosis and avitaminosis and in the prophylaxis of these conditions.

Recently, much attention has been paid to the megadosing of vitamins, i.e., the controlled administration of vitamins in doses which exceed by far the physiological intake.

The following applications can be differentiated:

1) Combating deficiency diseases, e.g., megadoses of vitamin K for infants and small children in developing countries
2) Prophylactic or therapeutic applications in the case of diseases which can cause vitamin deficiency
   a) Vitamin C for colds
   b) Fat-soluble vitamins in chronic disturbances of fat absorption (chronic Pauls reaction, chronic cholesterase)
   c) Megadoses of thiamin for alcoholics
3) Alleviation of vitamin metabolic diseases
   a) Megadoses of vitamin D in cases of chronic kidney insufficiency
   b) Megadoses of biotin in cases of multiple carboxylase deficiency

A survey of the use of megadoses of vitamins in prophylaxis and therapy is given in [9].

Hyperdosing can occur in the case of the fat-soluble vitamins A and D because they can be

[a] 1 mg retinol equivalent = 6 mg all-*trans*-β-carotin = 12 mg other provitamin A carotinoide = 1.15 mg all-*trans*-retinyl acetate = 1.83 mg all-*trans*-retinyl palmitate.

[b] 1 mg (*RRR*)-α-tocopherol equivalent = 1.1 mg *RRR*-α-tocopheryl acetate = 2 mg (*RRR*)-β-tocopherol = 4 mg (*RRR*)-γ-tocopherol = 100 mg (*RRR*)-δ-tocopherol = 3.3 mg (*RRR*)-α-tocotrienol = 1.49 mg all-*rac*-α-tocopheryl acetate.

[c] 1 mg niacin equivalent = 60 mg tryptophan.

[d] Calculated on the basis of "total folate" (sum of folate-active compounds in normal food).

[e] Folate equivalent or free folic acid (pteroyl monoglutamate).

stored and can be eliminated only by conversion to excretable substances. To prevent toxic side effects, controlled administration is necessary.

1.6. Studies with Vitamins

The effects of overdoses of vitamins (vitamin C, E, β-carotene) in the prevention of cancer and coronary heart diseases are being studied in a series of investigations.

A summary of the studies on the effects of antioxidative vitamins is given in Table 5.

An evaluation of these studies shows that the intake of certain vitamin/carotene combinations has a prophylactic effect. Further information on these results is given in [10–12].

1.7. Use of Vitamins in Food- and Feedstuffs

For humans, the most important sources of vitamins are plant and animal foods. In the industrial countries, the vitamin requirement can be completely covered by the food consumed. Nevertheless, the danger of a suboptimal supply exists in large segments of the population of these countries. According to the nutritional report of the Deutsche Gesellschaft für Ernährung (German Society for Nutrition), the supply of the vitamins B_1, B_2, and B_6 is regarded as critical in Germany [13].

The reasons for this are the one-side preference for certain foods and a steady transition from fresh, home cooked meals to the consumption of canned foods and mass catering. The industrial production of foods, which requires preservation in most cases to give long shelf lives, results in a considerable loss of vitamins due to the effect of heat, air, and light. To compensate for these losses, fortification of basic foods (flour, bread, and cakes with B complex vitamins; margarine and milk products with vitamins A, E, and D) diet foods (e.g., baby foods containing all the vitamins) and fruit juices (vitamin C, etc.) is gaining importance. For legal aspects, see [14].

In the feed industry, vitamins are used on a large scale as additives in animal feeding to ensure an optimal supply.

Breeding diseases, fertility losses, and performance changes of all types are avoided by the selective feeding of vitamins, improving profitability in animal husbandry. This applies especially to today's intensive farming of poultry, fish, and pigs and to calf breeding with milk substitute.

In Germany, the type and quantity of feed additives that are mixed with the different kinds of feedstuffs are stipulated by the feed law [15].

1.8. Antivitamins

Antivitamins are compounds that reduce or reverse in a specific manner the effect of vitamins. A distinction is made between compounds which destroy or capture the vitamin, and substances which compete with the vitamin for the binding site on the receptor (competitive inhibition).

Examples of the first class of compounds are, e.g., thiaminase, which cleaves the vitamin thiamine, and avidin, which forms a complex with biotin, making it unavailable for the body.

Antivitamins can be used to produce defined vitamin deficiency diseases, allowing the biochemical background of vitamin activity to be studied.

Some antivitamins are therapeutically applied, e.g., folic acid antagonists in the treatment of certain forms of leukemia and vitamin K antagonists as inhibitors of clotting.

1.9. Analysis of Vitamins

Methods of determination for vitamins which are based on the specific properties of vitamins include biological, microbiological, and enzyme activation processes.

Biological methods are mostly growth tests with experimental animals fed vitamin deficient diets. They were important especially for the checking the progress of enrichment during the isolation of vitamins. Today, these processes are used only for special purposes because they are difficult and tedious to conduct and evaluate and, consequently, inaccurate.

Microbiological methods are based on the fact that various vitamins are growth factors for certain microorganisms. The photometrically measurable turbidity of the culture medium

Table 5. Summary of studies on the effects of antioxidative vitamins

Period	Vitamin	Participants	Country	Results
1970 – 1980	β-carotene	3000 men	USA	the men who died of cancer during the study had 20 % less β-carotene in the blood than control persons
1980 – 1990	β-carotene, vitamins E, C	2000 nurses recovered from cardiac infarct or angina	USA	antioxidant vitamins reduce the risk of cardiac infarct by 33 % and stroke by 71 %
1985 – 1991	β-carotene, vitamin E	29 000 smokers	Finland	no preventive effect was detected during the study
1985 – 1991	β-carotene, vitamin E, Se	30 000 smokers	China	vitamins reduce risk of cancer
1991 – 1992	β-carotene, vitamin E	1400 persons: 50 % with acute cardiac infarct, 50 % control persons	Europe	infarct patients have a lower β-carotene and vitamin E status
1988 – 1992	β-carotene, vitamins E, C	900 patients with removed adenomas	USA	the treatment does not influence the probability of formation of new adenomas
1989 – 1994	β-carotene	400 albinos with skin diseases	Tanzania	β-carotene reduces the development of skin cancer
1990	β-carotene, vitamins E, C	500 men	UK	low plasma concentrations correlate with high risk of angina
1986 – 1990	vitamin E	40 000 men	USA	vitamin E reduces the risk of severe heart diseases by 37 %
1980 – 1988	vitamin E/multi-vitamin preparation	37 000 women	USA	vitamin E reduces the risk of coronary diseases by 40 %

is a measure of the vitamin concentration. Microbiological methods are characterized by high specificity and accuracy. They are used for the determination of vitamins in biological material and in pharmaceutical preparations (e.g., vitamins of the B group).

For clinical investigations (e.g., measurement of the vitamin level in the blood and urine), enzyme activation is commonly used because of its high specificity. It is based on the addition of the specific apoenzyme of the vitamin (coenzyme) to be determined and subsequent measurement of the activity of the holoenzyme.

The chemical and physical methods of determination used correspond to the normal methods for the analysis of organic substances. Modern chromatographic processes are particularly important.

In the case of vitamin preparations, the concentrations given refer to the quantity by weight. Only for vitamins A, D, and E, it is customary to state the international units as well.

1.10. Production

Vitamins are produced on an industrial scale by chemical synthesis or partial synthesis, by fermentation, or by extraction from natural material, whereby chemical synthesis is the dominant method.

The production processes used commercially are summarized in Table 6.

Table 6. Typical processes for the commercial production of individual vitamins ∗

Vitamin	Synthesis	Fermentation	Isolation

Niacin	+		
Pantothenic acid	+		
		○	

∗ + Commercially used; ○ commercially possible.

Many vitamins have become large-scale products because of the constantly increasing

demand. The economic importance of the vitamins has increased to the same extent. At present, the worldwide market value for vitamins as a bulk product is ca. 26×10^9 €/a. In terms of value, the feed industry accounts for ca. 50 %, the pharmaceutical industry for ca. 30 %, and the food industry for ca. 20 %.

2. Vitamin A (Retinoids)

2.1. Introduction

In the broadest sense, the term vitamin A refers to a group of monocyclic diterpenes with similar biological activity. Since the term vitamin A is frequently linked to vitamin A alcohol [(all-*E*)-3,7-dimethyl-9-(2,6,6-trimethyl-1-cyclohexenyl)-2,4,6,8-nonatetraen-1-ol, retinol, vitamin A_1], and a large number of other natural and synthetic vitamin A derivatives exist, the designation retinoids is often employed [31].

In addition to retinol (**1**), there are retinoids that can be distinguished by their side chain and their ring system. These include retinal (**2**), retinoic acid (**3**), retinyl phosphate (**4**), the 3-dehydro compounds (**5**), (**6**), (**7**), and retroretinoids (**8**), (**9**), (**10**).

1 R = CH_2OH: retinol [*68-26-8*]
2 R = CHO: retinal [*116-31-4*]
3 R = CO_2H: retinoic acid [*302-79-4*]
4 R = $CH_2OPO_3H_2$: retinyl phosphate [*53859-19-1*]

5 R = CH_2OH: 3-dehydroretinol [*79-80-1*]
6 R = CHO: 3-dehydroretinal [*472-87-7*]
7 R = CO_2H: 3-dehydroretinoic acid [*4159-20-0*]

8 R = CH_2OH: retroretinol [*27597-84-8*]
9 R = CH_2OAc: retroretinyl acetate [*7631-44-9*]
10 R = CH_2: anhydroretinol [*16729-22-9*]

Vitamin A is found only in animal tissue, whereas the carotenoids known as provitamin A are found in the plant world. The latter are oxidatively degraded to vitamin A compounds in the animal organism.

The important provitamins A are β-carotene (**11**), α-carotene (**12**), γ-carotene (**13**), β-apo-8′-carotinal (**14**), β-carotene-5,6-epoxide (**15**), cryptoxanthin (**16**), and echinenone (**17**).

Provitamin A activity requires at least one cyclohexene or 5,6-epoxycyclohexane ring and one polyene chain equivalent with a chain length corresponding to that of vitamin A.

2.2. Historical Aspects

In 1876, SNELL showed that cod-liver oil could cure night blindness and xerophthalmia [32].

In 1880, LUNIN found that the growth and vital functions of experimental animals could not be maintained with carbohydrates, fats, and proteins alone, but that the addition of small quantities of milk powder was also required [33].

In 1909, STEPP extracted vital fat-soluble substances from milk [34]. In 1916, MCCOLLUM made a distinction between "fat-soluble A" and "water-soluble B" [35]. Later, the fat-soluble agent was called "vitamin A" on the proposal of DRUMMOND [36]. (The name "vitamin" had already been suggested by FUNK in 1912 when he isolated the anti-beriberi agent thiamin [37]).

Progress in the concentration of retinol (**1**) was made only after its sensitivity to oxygen and higher temperatures was recognized and the connection between the growth promoting effect and the color intensity in the Carr – Price test was discovered [38]. In 1931, KARRER isolated almost pure retinol (**1**) from the oil of a type of mackerel (*Scom-bresox saurus*) [39]. The first crystalline preparations were made in 1937 by HOLMES and CORBET [40] and in 1942 by BAXTER and ROBESON [41], who also succeeded in isolating crystalline (13*Z*)-retinol in 1946 [42]. The compound 3-dehydroretinol (**4**) was found in the liver oil of freshwater fish in 1937 [43], isolated in 1948 [44], and obtained in the crystalline form in 1962 [45]. As early as 1831, WACKENRODER [46] succeeded in isolating the orange-yellow pigment of the carrot (*Daucus carota*) which he called carotene. The wide distribution of carotene in the plant world was described by ARNAUD in 1887 [47]. It was only after improved isolation methods became available that the production of pure preparations was possible. In the course of this work, WILLSTÄTTER in 1907 was able to establish the empirical formula of carotene [48], which was thought to be a homogeneous compound.

In 1931 KUHN, KARRER et al. succeeded in isolating optically active α-carotene (**8**) by fractionated crystallization or chromatography on calcium hydroxide [49]. Of importance for the structural elucidation of the carotenoids was the discovery that the chromophoric group consists of conjugated olefinic double bonds [50]. From the amount of hydrogen absorbed in catalytic hydrogenation, it was calculated that carotene has 11 and the isomeric lycopene has 13 double bonds [51]. In 1929, the provitamin A activity of carotene was unambiguously demonstrated in animal experiments and it was simultaneously shown that the other carotenoids known at that time were completely inactive in this respect [52]. Thus, further experiments for elucidating the structures of carotene and vitamin A were closely connected. Important progress in determining the structure was made by means of oxi-dative degradation with potassium permanganate, chromic acid, and ozone to give characteristic fragments [53]. One of the first correct suggestions for the structure of retinol (**1**) was made by KARRER who had shortly before determined the structure of β-carotene [54]. The constitution of 3-dehydroretinol (**4**) was long disputed and finally established with its synthesis in 1952 [55].

In 1937, KARRER obtained β-apo-8′-carotinal by oxidative degradation of β-carotene with potassium permanganate [56]. The compound β-apo-8′-carotinoic acid ((**14a**) with X = OH) was isolated from egg yolk after feeding laying hens with **14** [57].

2.3. Physical Properties

The melting points and the UV spectroscopic data of vitamin A compounds and their most important derivatives are presented in Table 7.

Retinol (**1**), retinal (**2**), and the dehydro compounds **5** and **6** are readily soluble at room temperature in fats, oils, and common organic solvents. In contrast, retinoic acid (**3**) is appreciably soluble only in chlorinated hydrocarbons.

High-vacuum distillation can be used for the purification of retinol (**1**), its esters, and retinal (**2**) (retinol at 125 °C, retinyl acetate at 132 °C and 400 Pa). The double bonds in the side chain also allow the existence of *Z* isomers, some of which occur in nature. Thus, (all-*E*)-retinol is frequently accompanied by the (13*Z* isomer (**18**). The compound (11*Z*)-retinal (**19**) is of importance as the prosthetic group of the protein opsin [58].

3-Dehydroretinal	78 – 79	(314), 401	395, 1470	
3-Dehydroretinoic acid	183 – 184	(305), 370	443, 1395	

∗ The values refer to the (all-*E*) isomers unless otherwise noted.
∗∗ Curative growth test in rats.

In comparison with the other stereoisomers of retinoic acid, (9*Z*)-retinoic acid (**20**) exhibits the highest binding affinity for the nuclear receptor RXR α [59], resulting in an altered gene expression as a consequence of direct ligand interaction.

20 [*5300-03-8*]

With four double bonds in the side chain of vitamin A, 16 stereoisomeric forms (*E* and *Z* isomers) are theoretically possible. In the individual isomers, the steric effects allow a distinction to be made with regard to the stability of hindered and unhindered *cis* forms. While the trisubstituted double bonds (9 and 13) of the side chain are quite stable in the (*Z*) configuration, the disubstituted bonds (7 and 11) rearrange readily to the (*E*) form (**21**) [60].

21

In the case of unhindered *cis* double bonds, the 1,4 steric interaction of two H atoms is weak, but strong interaction occurs between a H atom and a methyl group or between two methyl groups in hindered *cis* double bonds. Therefore, facile isomerization from the hindered *cis* forms to the *trans* forms is observed.

Thus, the four stable retinal isomers (all-*E*; 9*Z*; 13*Z*; 9*Z*,13*Z*) are well known. Of the remaining 12 isomers, however, only four of the labile forms (7*Z*; 11*Z*; 7*Z*,9*Z*; 11*Z*,13*Z*) are known [61]. Other labile *Z* forms have been synthesized under special conditions [62, 63].

X-ray analyses of retinol (**1**), its esters [64], and retinal (**2**) [65] assign a 6,7-*s*-*cis* conformation to the molecule in the crystal lattice.

Two different crystal modifications of retinoic acid have been determined [66]. In addition to the stable 6,7-*s*-*cis* form (**22**, triclinic modification), the labile 6,7-*s*-*trans* form (**23**, monoclinic modification) is also known.

6,7-*s*-*cis*-form **22** 6,7-*s*-*trans*-form **23**

In the all-*trans* forms, the polyene chain has a saber-like curvature which results from the interaction of the methyl group in the side chain with the hydrogen on the next carbon atom but one.

The provitamins A have colors which vary from bright yellow to red, due to the system of conjugated double bonds.

With increasing numbers of double bonds and with the introduction of carbonyl groups conjugated to the double bond system, the maxima in

the UV and visible region shift to longer wavelengths.

The melting points, UV spectroscopic data, and biological activity of the most important provitamins A are listed in Table 8.

Both α- and β-carotene (**12** and **11**) are readily soluble in chlorinated hydrocarbons and in carbon disulfide, and poorly soluble in ether, lower alcohols, and in aromatic or aliphatic hydrocarbons. In comparison with the carotene hydrocarbons (**11**) and (**12**), the β-apocarotenoids are in general more readily soluble. Data on the solubility of (all-*E*)-β-carotene (**11**) in g/100 mL at 20 °C follow:

Water	0.0
Ethanol	< 0.01
Fats and oils	0.05 – 0.08
Orange oil	0.2 – 1
Cyclohexane	ca. 0.1
Ether	ca. 0.1
Acetone	ca. 0.1
Chloroform	ca. 3

The provitamins A occur in fresh plant tissue in the (all-*E*) form. During drying and storage, however, partial conversion to the *Z* forms takes place. Heating in solution or in the presence of iodine causes isomerization. This process produces all-*E* compounds as well as 9*Z* and 13*Z* forms as the main components. In comparison with the all-*E* compounds, the *Z* isomers have a lower extinction and biological activity [67].

Table 9. Typical reactions of retinoids. In principle, they also apply to the 3-dehydro forms.

Retinoids	Reagents	Products
Retinol	manganese dioxide	retinal (**2**) [68, 69]
	acetic anhydride (Ac_2O)	retinyl acetate
	palmitoyl chloride	retinyl palmitate
	maleic anhydride	Diels – Alder adducts
	singlet oxygen	5,8-peroxide (**24**) [70]
	peroxy acids	5,6-epoxide (**25**) [71]
	ozone	geronic acid
	potassium permanganate	acetic acid
Retinal	sodium borohydride	retinol [72]
	silver oxide	retinoic acid [73]
	manganese oxide	4-oxoretinal [74]
Retinoic acid	alcohols	retinoic esters
	glucuronic acid	glucuronides
	lithium aluminum hydride	retinol [75]

2.4. Chemical Properties

Retinol (**1**) and its esters are readily oxidized by atmospheric oxygen and other oxidizing agents, especially in the presence of light or at higher temperatures. The addition of antioxidants (e.g., α-tocopherol) or storage in the cold with the exclusion of light and oxygen ensures a certain stability. Some typical reactions of vitamin A are listed in Table 9.

24 [*29443-90-1*] **25** [*801-72-9*] **26** [*744-98-9*]

In all these reactions, the stereochemistry of the polyene side chain remains unchanged provided light and oxygen are excluded.

Vitamin A is resistant to bases, but retinol (**1**) and its esters undergo rearrangement and elimination reactions in the presence of acids. Dilute acids cause the conversion of retinol (**1**) to anhydroretinol (**10**).

In dichloromethane, retinyl acetate is converted in the presence of hydrogen bromide to retroretinyl acetate (**9**) within seconds. The treatment of vitamin A compounds with halogenating agents (e.g., *N*-bromosuccinimide) results in the preferential halogenation of the methylene group at position 4. Subsequent base-catalyzed elimination of hydrogen halide provides access to the 3-dehydroretinoids (**5**, **6**, **7**), which, however, have no significant vitamin A activity. Strong Lewis acids react with vitamin A to produce characteristically colored complexes (e.g., blue color of complex with $SbCl_3$ in the Carr – Price reaction), which form the basis of analytical identification [76]. With dienophiles (e.g., maleic anhydride), retinol (**1**) and its esters undergo typical [4 + 2] cycloaddition reactions. The 11,13-di-*trans* configuration reacts preferentially, allowing easy differentiation and separation of the all-*trans* and 9-*cis* compounds from the slower reacting 13-*cis*, 11-*cis*, 11,13-di-*cis*, and 9,13-di-*cis* stereoisomers [82].

The provitamins A are also sensitive to oxidation. The degradation of β-carotene with potassium permanganate leads to β-apo-12′- and β-apo-8′-carotinal (**14**) [77]. Chromic acid cleaves the ring double bond with formation of open-chain diketones [78]. Peroxy acids preferentially give 5,6-epoxides, which rearrange to 5,8-di-

Table 8. Characteristic data of the most important provitamins A [(all-E) isomers]

Compound	*mp*, °C	UV absorption (in Ethanol)		Biological Activity
		λ, nm	$\varepsilon_{1\,\mathrm{cm}}^{1\,\%}$	in % ∗
β-Carotene	182 – 183	456, 484	2500, 2200 (Cyclohexane)	100

∗ Curative growth test in rats.

hydrofuran derivatives (**26**) under acid catalysis [79].

The reaction of provitamin A with *N*-bromosuccinimide or iodine preferentially leads to 4,4′-dihalo compounds [80], which allow the synthesis of 4,4′-dioxo-β-carotene (canthaxanthin) by continued oxidation [81].

The *E,Z* isomeric vitamin A compounds differ considerably in their biological activity [83]. The highest activity is exhibited by (all-*E*)-retinol and its esters (see Table 7). Industrially, retinyl acetate is isomerized either photochemically [84] or in the presence of catalytic amounts of iodine or palladium compounds [85]. The all-*E* form, which predominates at equilibrium, can be separated by crystallization from hexane or methanol.

2.5. Occurrence

Retinol (**1**) occurs exclusively in animal organs, especially in the liver. Generally, it is esterified with higher fatty acids (e.g., palmitic acid). Relatively high concentrations are found in milk, eggs, and blood plasma.

Vitamin A is largely formed by degradation of carotenoids ingested with food. Carotenoids are synthesized only by higher plants and microorganisms. After consumption carotenoids, also known as provitamins A, are enzymatically converted to vitamin A, especially in the cells of the intestinal mucosa [86]. The compounds α- and β-carotene (**12** and **11**) are permanent companions of chlorophyll. High concentrations are found especially in paprika, carrots, and in palm oil (400 – 800 ppm) [87], which is used to color edible fats. The β-apo-carotinals mainly occur in citrus fruits. However, their concentration is too low to permit economic commercial isolation [88].

2.6. Biosynthesis

In the animal organism, vitamin A compounds occur as metabolites of the provitamins A, especially of β-carotene (**11**).

The C_{40} carotenoids are tetraterpenes. They are biosynthesized according to the principle valid for all terpenes [89] (see Scheme 1; → Terpenes, Chap. 1.3.). The C_5 structural unit 1-isopentenyl pyrophosphate (**28**) is made from three molecules of acetyl coenzyme A via mevalonic acid (**27**). Isomerization of **28** gives the more reactive 3,3-dimethylallyl pyrophosphate (**29**). The linkage of these two components starts a chain of alkylation steps which leads to the C_{20} intermediate geranylgeranyl pyrophosphate (**30**) and is interrupted by dimerization to give (15*Z*)- or (all-*E*)-phytoene ((**32a**) and (**32b**)), the first C_{40} carotenoid. The intermediate in this reaction is prephytoene pyrophosphate (**31**). Dehydrogenation of **32** gives lycopene (**33**) via phytofluene, ζ-carotene, and neurosporin. From lycopene, α- and β-carotene (**12** and **11**) are formed by stepwise cyclization.

The subtle stereochemical problems involved in the individual steps have been elucidated by the use of mevalonic acid (**27**), stereospecifically labelled at the prochiral centers C-2, C-4, and C-5 (**27′**). Thus, it is known that the anhydrodecarboxylase step **27** → **28** proceeds as a trans elimination. In the isomerase reaction **28** → **29**, a proton is added at the *re,re* side of the double bond, followed by eliminaton of the 2-*pro-R* proton of **28** (H_{4S} of **27′**).

The prenyltransferase steps **29** →**30** also proceed with elimination of the 2-pro-R proton (Scheme 1) of **28** and with inversion at C-1 of the allylpyrophosphate components (C-5 of **27′**). An enzymatic addition – elimination mechanism leads to *E* double bonds.

In the linkage of two molecules of geranylgeranyl pyrophosphate (**30**) to form (15*Z*)-phytoene (**32a**), the 5-*pro-S* hydrogen atoms of mevalonic acid are lost. In the dehydrogenation **32** → **33**, double bonds in the *E* configuration are introduced stepwise with the elimination of one 2-*pro-S* and one 5-*pro-R* hydrogen atom of mevalonic acid (**27′**).

The cyclization **33** → **11** or **12** is started by,*re,re* addition of a proton to C-3 of the terminal double bond (C-4 of **27′**) and intramolecular alkylation of the 6,7 double bond. Cleavage of a proton from C-6 and C-4 (C-4 and C-2 of **27′**) results in the parallel formation of the α- and β-ionone rings. The methyl group from C-2 of mevalonic acid (**27′**) occupies the *pro-S* position.

From a stereochemical standpoint, the reaction sequence can be represented by the labelling scheme **27′** → **30′** → **33′** → **12′** (Scheme 2).

The conversion of the provitamins A to vitamin A compounds takes place in the intestinal mucosa. In this process, α- and β-carotene (**12** and **11**) are cleaved by oxygen in the presence of carotene 15,15′-dioxygenase into two molecules of retinal (**2**) [90]. Similar enzymes also catalyze the oxidative degradation of β-apocarotinals [91]. Retinal (**2**) is predominantly reduced to retinol (**1**) and partly oxidized to retinoic acid (**3**).

After transfer into the intestinal cells, retinol (**1**) is esterified with higher fatty acids and released into the lymph in this form [92]. After the direct vitamin requirement of the organism is covered, the retinyl esters are stored in the liver [93]. Free retinol (**1**) predominates in the blood stream; a specific protein is responsible for transport [94].

2.7. Production

2.7.1. Isolation and Purification from Natural Raw Materials

Owing to the sensitivity of retinol (**1**) to air, higher temperatures, and acids, it must be isolated under especially mild conditions (extraction with organic solvents under protective gases, e.g., CO_2, N_2). Since retinol (**1**) and its esters occur in the free form in tissues and organs, the first concentration step can be extraction with heptane. For retinal (**2**), however, special isolation methods are required because it is covalently bound to primary amino groups in the form of a Schiff's base [95].

In general, vitamin A is isolated by liquid–liquid extraction, molecular distillation [96], and HPLC [63]. Commercial isolation of retinol (**1**) from natural raw materials starts with fish oils and is conducted in six steps: (1) accumulation of crude vitamin A by the Solexol countercurrent extraction process [97], (2) short-path distillation of the retinyl esters (200 °C, 400 Pa), (3) ester saponification (KOH, 60–70 °C, 30 min, N_2), (4) extraction of retinol (**1**) with ether, (5) short-path distillation of retinol (**1**) (120 °C, 400 Pa), and (6) final purification by crystallization from ethyl formate (−35 °C).

With the development of efficient processes for the synthesis of vitamin A on a commercial scale, isolation from natural raw materials has lost importance.

2.7.2. Industrial Synthesis

Since retinol (**1**) was first synthesized by KUHN [98], numerous strategies for its synthesis have been developed. Vitamin A is formed by the linkage of various cyclic components with the corresponding open-chain compounds [99, 100]: $C_{10}+C_{10}$ [101], $C_{11}+C_9$ [102], $C_{13}+C_7$ [103], $C_{14}+C_6$, $C_{15}+C_5$, $C_{16}+C_4$, $C_{18}+C_2$, and $C_{18}+C_1+C_1$.

The key building block of all industrial vitamin A syntheses is β-ionone (**34**), which can be made from citral (**35**) [104] and acetone or from

Scheme 1.

Scheme 2.

dehydrolinalool (**36**) [105] and diketene [106] or isopropenyl methyl ether [107] via pseudoionone (**37**) [108].

Synthesis of the C_{20} Skeleton of Vitamins A. $C_{15} + C_5$ *(Sumitomo)* [109]. Knoevenagel condensation of β-ionylidene acetaldehyde (**38**) [110] with (*E*)-3-methyl-2-butenoic ester using potassium amide in ammonia produces (all-*E*)-retinoic ester (**39**). Reduction with lithium aluminum hydride and subsequent acetylation yields retinyl acetate (**40**).

$C_{16} + C_4$ *(DPI, Glaxo)* [111]. The reaction of β-ionone (**34**) with 2-propinyl chloride in the presence of zinc yields β-propargyl-β-ionone (β-C_{16} alkinol) (**41**). Grignard reaction with 4,4-dimethoxy-2-butanone (**42**), followed by partial hydrogenation and hydrolysis of the acetal as well as elimination of water, gives retinal. Retinal is then converted to retinyl acetate (**40**) by reduction and subsequent acetylation.

$C_{18} + C_2$ *(Philips)* [112]. β-Ionone (**34**) and the homologous β-C_{18} ketone (**43**) are converted to β-ionylidene acetaldehyde (**38**) and retinal (**2**) by condensation with cyanoacetic ester and reduction of the nitriles **44** and **45** with diisobutyl aluminum hydride. The β-C_{18} ketone (**43**) is made from β-ionylidene acetaldehyde (**38**) by condensation with acetone.

$C_{18} + C_1 + C_1$ *(AEC)* [113]. Starting with β-ionone (**34**) and β-C_{18} ketone (**43**), a stepwise conversion to β-ionylidene acetaldehyde (**38**) and retinal (**2**) is carried out. Condensation of the ketones **34** and **43** with formic ester gives the β-C_{14} and β-C_{19} enolates, which yield the hydroxyacetals **48** and **49** after acetal formation (**46** or **47**) and Grignard reaction. Subsequent acetal hydrolysis and water elimination give the final products of the reaction sequence **38** and **2**.

$C_{14} + C_6$ *(Hoffmann LaRoche)* [114]. β-Ionone (**34**) is converted to the β-C_{14} aldehyde (**50**) in a Darzens glycidic ester synthesis [115,116]. Subsequent Grignard reaction with 3-methyl-2-penten-4-in-1-ol(**51**) yields the C_{20}alkynediol (**52**).

(All-*E*)-retinyl acetate (**40**) is obtained after partial hydrogenation of the triple bond to give the (11*Z*, 13*Z*) compound **53**, acetylation of the

primary hydroxyl group, and subsequent acid-catalyzed dehydration with isomerization of the double bonds into the *E* configuration.

The C_6 structural unit **51** is made from methyl vinyl ketone by ethynylation and alkyl rearrangement of the tertiary alkyne carbinol **54** [117].

$C_{15} + C_5$ *(BASF)* [118] (Scheme 3). The synthesis of the C_{20} skeleton is achieved by using the Wittig reaction [119]. Alkylidenetriarylphosphanes are obtained from alkyltriarylphosphonium salts by treatment with base [120–122]. The formation of olefins with simultaneous release of triarylphosphine oxide is achieved by condensation of these alkylidene triarylphosphanes with carbonyl compounds [123].

The C_{15} phosphonium salt **56** can be made from β-ionone (**34**) in two different ways. β-Vinylionol (**55**) is obtained by ethynylation and subsequent partial hydrogenation [124] or by vinylation [125]. Treatment with triphenylphosphine and acid yields the C_{15} phosphonium salt **56** [126], the key building block for the synthesis of retinoids. Retinyl acetate (**40**) is prepared by Wittig reaction with the C_5 aldehyde **57**, which is accessible by various routes [127, 128], e.g., by rhodium-catalyzed hydroformylation of 1,2-diacetoxy-3-butene (**58**) [129]. Coupling of **56** with **57** is carried out in organic solvents such as alcohols or DMF, or in aqueous solution with mild bases (e.g., alkali metal carbonate or ammonia) [130]. In this way, a mixture of the double bond isomers 11*Z* and all-*E* is obtained in a yield of ca. 90 %. The labile 11*Z* isomers can be converted to the all-*E* form in various ways [131].

If the C_{15} phosphonium salt **56** is reacted with the alternative C_5 building blocks **59** [132], **60** [133], or **61** [134], retinal (**2**), retinoic acid (**3**), or (13*Z*)-retinoic acid (**62**) is obtained [if necessary after hydrolysis and isomerization of the (11*Z*) form].

$C_{15} + C_5$ *(Rhône-Poulenc)* [135] (Scheme 4). This synthesis of vitamin A is based on a two-step olefin synthesis [136] using Julia sulfone chemistry. Allyl phenyl sulfones are metalated in the α-position and alkylated with alkyl halide. The double bond is formed by elimination of benzenesulfinic acid. The coupling and elimination steps both require comparatively strong bases such as potassium *tert*-butoxide or other alkali metal alkoxides [137].

Scheme 3.

Scheme 4.

Scheme 5.

As in the BASF process, the C_{15} building block is obtained from β-vinylionol (**55**). The reaction of β-vinylionol with sodium phenylsulfinate yields the C_{15} sulfone **63** [138].

Subsequent reaction of **63** with 1,1-dialkoxy-4-bromo-3-methyl-2-butene (**64**) [139] or 1-acetoxy-4-chloro-3-methyl-2-butene (**65**) [140] yields the C_{20} sulfones **66** or **67** [141]. Elimination of benzenesulfinic acid, followed by acetylation affords retinyl acetate (**40**) (if necessary after hydrolysis of the acetal group and reduction of the aldehyde [142]). While the C_5 building block **64** is obtainable from prenal [143], **65** is derived from isoprene [144].

Formation of the polyene skeleton is also possible by treating β-vinylionol (**55**) with γ-halogeno (**68**), γ-acetoxy (**69**) or γ-thiophenyl dienol ethers (**70**), catalyzed by Lewis acids [145]. The primary coupling products **71**, **72**, and **73** can be converted to retinyl acetate (**40**) via a reaction cascade (Scheme 5). The C_5 building blocks used are obtainable from prenal. A commercial application of this synthesis has not been realized.

$C_{10} + C_{10}$ *(Kuraray, Solvay – Duphar)* [146]. On the basis of sulfone chemistry, the synthesis of retinoids is achieved by coupling two C_{10} building blocks [147]. The common starting material for both compounds is myrcene (**74**) or linalool (**75**), which is converted in a multistep sequence to β-cyclogeranyl sulfone (**76**) and 8-acetoxy-2,6-dimethyl-2,6-octadienal (**77**) [148]. The β-hydroxysulfone **78** is obtained by α-metalation of the C_{10} sulfone **76**, followed by condensation with the C_{10} aldehyde acetate **77**. The β-hydroxysulfone is then converted to retinyl acetate (**40**) via the derivatives **79**, **80** [149] (Scheme 6).

$C_{13} + C_2 + C_5$ *(L'Oreal)* [150]. Starting from β-ionone (**34**), β-ethynylionol (**81**) is produced by ethynylation. In a subsequent Grignard reaction, coupling with β-formyl crotonate (**60**) is carried out, giving the corresponding acetylene ester **82**, which after reduction to the triol is selectively etherified at the primary alcohol group.

The resulting ether diol **83** is stereospecifically reduced to retinyl ether (**84**) after partial hydrogenation of the triple bond with a mixture of titanium trichloride and lithium aluminum hydride.

$C_{13} + C_2 + C_3 + C_2$ [151]. Another path leading to retinal (**2**) is via the vinylogization of carbonyl compounds with the formation of α,β-unsaturated aldehydes and methyl ketones. The building blocks for a synthesis of this type are 2-lithiovinyloxy(trialkyl)silanes (**85**) and 2-lithio-1-methylvinyloxy(trialkyl)silanes (**86**). In a further development of this reaction principle [152], retinal (**2**) is obtained with the C_5 building blocks **87**, **88** or with the C_7 building block **89** (Scheme 7).

More recently that concepts have been developed for the synthesis of polyenes via Heck coupling of C – C single bonds [153].

Scheme 6.

Scheme 7.

Synthesis of the C_{40} Skeleton of Provitamins A. The syntheses of the provitamins A are closely related to those of the vitamin A compounds.

$C_{19} + C_2 + C_{19}$ (Hoffmann LaRoche) [154]. β-Carotene is produced from the β-C_{14} aldehyde **50**, an intermediate in the synthesis of vitamin A. **50** is converted to the β-C_{19} aldehyde **90** in two steps: First, with ethyl vinyl and then with ethyl isopropenyl ether in a Müller – Cunradi reaction. Subsequently, two molecules of **90** are linked together by acetylene giving the C_{40} diol **91**, which after partial hydrogenation and dehydration yields β-carotene (**11**).

Other syntheses of β-carotene (**11**) are mainly based on the building principles $C_{15} + C_{10} + C_{15}$ and $C_{20} + C_{20}$. While the first synthetic sequence comprises the Wittig condensation between two molecules of C_{15} phosphonium salt **56** and 2,7-dimethyl-2,4,6-octatrien-1,8-dial (**92**) [155], β-carotene can also be made by the condensation of retinal (**2**) with retinyltriphenylphosphonium salt (**93**), obtainable from retinyl acetate (**40**) [156, 157].

The synthesis of β-carotene (**11**) is also possible by using the Julia reaction [158]. Retinyl phenyl sulfone (**94**) is made by the reaction of retinol (**1**) with sodium benzenesulfinate. α-

Scheme 8.

Metalation with potassium *tert*-butoxide to give the C_{40} sulfone **96** is followed by alkylation with retinylhalide (**95**). Subsequent elimination of sulfinic acid yields β-carotene (**11**) (Scheme 8).

A new concept for the synthesis of β-carotene (**11**) uses the precursors of the vitamin A process of Kuraray ($C_{10} + C_{10}$) **79** or **80**. After selective oxidation to the corresponding aldehydes **97**, **98**, these compounds are subjected to Wittig condensation with retinyltriphenylphosphonium salt (**93**) [159]. Subsequent double elimination results in formation of β-carotene (**11**).

Other processes for the synthesis of β-carotene are based on the linking of two identical C_{20} components. Both the reductive dimerization of retinal in a manner analogous to the McMurray reaction [160] with lithium aluminum hydride and titanium trichloride, as well as a modified Wittig condensation with oxidative coupling of retinyltriphenylphosphonium hydrogensulfate (**93**, $X = HSO_4^-$) [161] with potassium carbonate and hydrogen peroxide in aqueous solution yield β-carotene (**11**).

The coupling of the C_{20} sulfone **99** with retinal (**2**) and the reaction of two molecules of C_{15} sulfone **63** with the C_{10} dialdehyde **92** have been described in the literature as possible methods for the synthesis of β-carotene [162].

All syntheses of β-carotene initially produce mixtures of *E,Z* isomers. As a result of the good crystallization properties of the all-*E* form [163], these mixtures can be almost quantitatively isomerized to the all-*E* form under isomerizing conditions [164].

Synthesis of the C_{30} Skeleton of Apocarotenoids. The syntheses of β-apo-8′-carotenoids (**14**), (**14a**) follow the paths $C_{19}+C_6+C_2+C_3$, $C_{15}+C_{10}+C_5$, and $C_{20}+C_{10}$ [165].

$C_{19}+C_6+C_2+C_3$. Starting with the C_{14} aldehyde **50**, the C_{19} aldehyde **90** is made via enol ether condensation, followed by reaction with 2-methylpent-2-en-4-yne-1-al diethyl acetal (**100**) in a Grignard reaction. After acetal cleavage and dehydration, 15-dehydro-β-apo-12′-carotinal (**101**) is accessible. Subsequent acetal formation, enol ether condensation [166], and hydrolysis yields 15-dehydro-β-apo-10′-carotinal (**102**). Further enol ether condensation or Wittig reaction with the corresponding C_3 building blocks and subsequent partial hydrogenation allows the synthesis of **14** and **14a** [167].

$C_{15}+C_{10}+C_5$. Wittig condensation of the C_{15} phosphonium salt **56** with the C_{10} dialdehyde **92** first produces β-apo-12′-carotinal (**103**), which can be condensed to **14** or**14a** by further treatment with C_5 alkylidenephosphanes **104**, **105** [168].

$C_{20}+C_{10}$. Wittig condensation of cyclic C_{20} components with open-chain C_{10} building blocks allows the reaction of both retinal (**2**) with the corresponding C_{10} alkylidenephosphane (**106** with Y = OR or O) [169] as well as retinyl-(triphenyl)phosphonium salt (**93**) with C_{10} aldehydes (**107** with X = H or OR) [170] (Scheme 9). As with β-carotene, isolation of the

all-*E* isomer exploits its good crystallizability, which allows almost quantitative isolation under isomerization conditions [171].

2.8. Metabolism and Physiological Functions

2.8.1. Preformed Vitamin A

About 90 % of the vitamin A stored in the liver is in the form of retinyl palmitate. Free retinol

Scheme 9.

is esterified here. The liver has a high storage capacity for retinyl palmitate.

Mobilization from the liver occurs as required. Retinyl palmitate is enzymatically hydrolyzed and the resulting retinol is released into the blood plasma by means of a specific retinol binding protein (RBP) and transported to the target cell [172].

At the receptor of the target cell, retinol is passed on to a cellular RBP (CRBP). As required, retinol can now be used as such, metabolized to retinoic acid, or reesterified to retinyl palmitate, which can be stored in the cell for a short time and used to bridge a temporary deficit.

Vitamin A plays a number of roles in the organism, the most important being:

1) Growth, development, and differentiation of epithelial tissue. In these processes, retinoic acid is the active compound. Retinol only represents the precursor of retinoic acid. The mechanisms of action in this area are extremely complex and not yet fully elucidated.
2) Reproduction. Vitamin A is essential for the reproduction of higher animals. In men and male animals, it is required in the form of retinoic acid for testosterone synthesis, and as retinol for the maintenance of spermatogenesis [173]. In women and female animals, retinol is substantially involved in the healthy development of the placenta and the fetus.
3) Vision. In the retina, retinol (**1**) is dehydrogenated and isomerized to (11*Z*)-retinal (**19**) which condenses with the lysine residue of the protein opsin to give the aldimine, forming the light receptor rhodopsin. The action of light causes conversion of the chromophore from the 11*Z* to the all-*E* form (bathorhodopsin, lumirhodopsin). After a change in the conformation of the protein part (metarhodopsin), retinal (**2**) is released hydrolytically. This affects ion transport and membrane potentials, resulting in the generation of an optic nerve impulse. Vitamin A deficiency causes night blindness (nyctalopia).

In the purple membrane of *Halobacterium halobium*, (13*Z*)-retinal is bound to a protein as a Schiff's base (bacteriorhodopsin) [174]. On illumination, light energy can be converted to chemical energy ("proton pump", ATP synthesis) with the isomerization of the chromophore to the all-*E* form. Furthermore, vitamin A plays a role in the important metabolic step of glycoprotein synthesis [175] and is involved in maintenance of the immune system [176, 177].

2.8.2. β-Carotene

β-Carotene is resorbed from plant food in the small intestine to an extent of 30 – 60 %, depending on the added fat content [178]. In intestinal cells, part of the β-carotene is homolytically cleaved to retinal by the enzyme 15,15′-carotene dioxygenase. Retinal is, in turn, reversibly reduced to retinol by retinal reductase and, to a smaller extent, irreversibly oxidized to retinoic acid [179].

Apart from homolytic cleavage, heterolytic cleavage of β-carotene also occurs, producing various apo-carotinals. These substances are also converted to retinal, depending on the chain length.

That part of β-carotene that is not metabolized in the intestinal mucosa is transported to the target organs in lipoproteins, especially LDL,

and in erythrocytes and leukocytes. Here, further conversion occurs to retinol and retinoic acid via retinal or apo-carotinals. From the standpoint of the physiology of nutrition, it is assumed that the conversion of β-carotene to vitamin A is ca. 15 % [180]. The conversion decreases with increasing amount of β-carotene absorbed [181] and depends on the individual vitamin A status [182]. The activity of 15,15′-carotene dioxygenase appears to decrease with an increasing supply of vitamin A. Consequently, it is controlled by the supply of vitamin A. For this reason, hypervitaminosis A cannot result from β-carotene.

The β-carotene that is not metabolized to vitamin A can be resorbed unchanged by humans and has its own biological functions, independent of its provitamin A properties.

Like the other carotenoids, β-carotene is regarded as a natural physiological antioxidant. As a result of its ability to deactivate singlet oxygen [181] and to interrupt oxidative radical chain reactions (e.g., lipid peroxidations in cell membranes) [182], β-carotene has a protective function in cells and, therefore, has a preventive effect on a series of radical-induced degenerative diseases.

The following applications are known or are being discussed:

1) Protection of the skin from light and treatment of solar dermatosis and pigment anomalies [183, 184]
2) Prevention of various types of cancer, especially lung cancer [185]
3) Prevention of atherosclerosis [186]
4) Boosting of the immune functions [187]
5) Prevention of certain eye diseases such as cataract and macula degeneration [187]

2.9. Deficiency Symptoms and Requirements

Deficiency Symptoms. Vitamin A deficiency causes numerous symptoms such as disturbances of vision (night blindness), damage to the skin and mucous membranes, atrophies, and growth retardation.

Even if the exogenous supply of vitamin A is adequate, deficiency symptoms can arise due to a deficit of carotene 15,15′-dioxygenase and carrier protein [188], caused by insufficient protein supply (hypovitaminosis A syndrome in undernourished persons).

Requirements. In modern animal husbandry, green fodder is being increasingly replaced by ready-to-use feed. Since this industrially produced feed contains little provitamin A, it is enriched with vitamin A (especially retinyl acetate).

The vitamin A requirement for the maintenance and performance (growth, eggs, milk) of animals is largely dependent on the body weight and is in the range of 50 I.U. per kilogram of body weight per day. For optimal utilization of fodder (fattening) and optimal milking or laying capacity, daily doses of 100 – 200 I.U. per kg of body weight are recommended for working animals. Independent of its importance as provitamin A, β-carotene has a specific influence on the fertility of cattle (progesterone synthesis) and other animals [189].

German recommendations for the vitamin A supply of working and domestic animals [in I.U. retinol per kg of dry feed or per animal (∗) per day] are as follows:

Piglets	10 000 – 16 000
Porkers	5 000 – 10 000
Milk cows ∗	80 000 – 120 000
Horses ∗	30 000 – 60 000
Chicks, feedercocks	8 000 – 12 000
Layers, turkeys	8 000 – 12 000
Dogs	8 000 – 12 000
Cats	15 000 – 25 000
Fish	8 000 – 12 000
Beef cows ∗	40 000 – 70 000

For humans, the daily doses recommended by the German Society for Nutrition (DGE) are shown in Table 10.

2.10. Analysis and Standardization

Vitamin A. An unequivocal characterization of vitamin A can be achieved by its UV spectra, by color reactions, and from its biological activity. For purity testing, chromatographic methods (SFC, HPLC) have become the methods of choice and are essential for quantification and identification. Spectrophotometric determination is meaningful only at relatively high vitamin A concentrations [190] because even small

amounts of interfering impurities result in considerable errors. In this method, the UV absorption is measured and has a maximum between 325 and 328 nm depending on the solvent.

In colorimetric determination, the intensity of the blue color is measured at 620 nm after the addition of antimony(III) or antimony(V) chloride in trichloromethane (Carr – Price reaction). *Cis*, *trans* isomers give equally intense colors. Other characteristic color reactions with vitamin A are exhibited by concentrated sulfuric acid, tin chloride, arsenic trichloride, and boron trifluoride. The mechanism of these reactions has been described [191].

Although the colorimetric method is more sensitive than the spectrophotometric method, it is somewhat less accurate since the colors fade relatively quickly. Exact determination of vitamin A is possible by fluorometry, a very sensitive and specific detection method [192, 193]. However, carotenoids and tocopherol [194] interfere with the analysis. The fluorimetric test is more effective in the presence of holo-retinol binding protein (holo-RBP) [195] because retinol bound to apo-RBP (i.e., holo-RBP) fluoresces 14 times more intensively than free retinol dissolved in a hydrocarbon. Holo-RBP can easily be separated electrophoretically in polyacrylamide gel and purified. Fluorimetric determination can be carried out directly on the electrogram.

Table 10. Vitamin A requirement of humans in retinol equivalents

Age	Retinol, mg RE ∗		
	m	m/f	f
0 – 4 months		0.5	
4 – 12 months		0.6	
1 – 4 years		0.6	
4 – 7 years		0.7	
7 – 10 years		0.8	
10 – 13 years	0.9		0.9
13 – 15 years	1.1		1.0
15 – 19 years	1.1		0.9
19 – 25 years	1.0		0.8
25 – 51 years	1.0		0.8
51 – 65 years	1.0		0.8
> 65 years	1.0		0.8
Pregnant women			1.1
Nursing women			1.8

∗ 1 mg Retinol Equivalent = 6 mg
all-*trans*-β-carotene = 12 mg other provitamin A carotenoids.
mg Retinol Equivalent is the official unit of vitamin A activity.
1 mg RE corresponds to 3333 I.U.

Biological methods [196] are based on the curative and prophylactic growth test in the rat, the colpokeratosis test in the rat and mouse, the antiestrus test, the liver storage test in the rat, and the curative xerophthalmia test. These tests are laborious and are mainly used to check the accuracy of new methods for the determination of active substances and to determine the total concentration of active vitamin A compounds.

Today, the separation of retinoids of the same polarity (e.g., *cis*, *trans* isomers) is exclusively conducted with high-pressure liquid chromatography (HPLC). Detection systems range from simple UV detection to electrochemical processes [197] and laser photoionization [198, 199].

Provitamin A. For the determination of provitamins A, spectrophotometric measurement of the absorption maximum is the most important method. If necessary, the substances are first purified on basic or neutral alumina, calcium oxide, magnesium oxide, or silica gel. Separation of structural isomers (*cis*, *trans*) is achieved by using HPLC [200].

2.11. Trade Names and Economic Aspects

Retinol (**1**) is sold almost exclusively in the form of the more stable esters (mainly as retinyl acetate, also as retinyl palmitate and propionate). About 80 % of the production is used in animal feed, the remainder in the food and pharmaceutical sectors.

For practical reasons, various preparations are made and mostly stabilized with antioxidants: solutions in fats and oils (food sector, especially margarine); liquid, water-miscible dispersions containing emulsifiers (pharmaceutical sector, animal feed); and, above all, dry powders which contain the agent embedded in a matrix of gelatin and/or polysaccharides (especially animal feed, and specialities in the food and pharmaceutical sectors).

At present, world production is ca. 2700 t/a. The producers are Hoffmann LaRoche (Switzerland and United States), BASF (Germany) and Rhône-Poulenc (France) as well as smaller producers in India, China, and the CIS. The market price is 200 – 250 DM/kg (calculated on the basis of 100 % active agent) depending on the preparation.

Retinoic acid (for acne) and (13*Z*)-retinoic acid (for psoriasis) have attained importance in dermatology.

The economic importance of the carotenoids, especially of β-carotene, has increased significantly in the past years and is still increasing.

In the form of oily dispersions, β-carotene is used to color margarine and other high-fat foods. As an active agent (see Section 2.8.2.) or as provitamin A, these dispersions are being increasingly filled into soft gelatin capsules.

Water-dispersible dry powders are used to color beverages, pudding powders, and many other foods. They are also employed as provitamin A in vitamin drinks or tablets.

In the animal feed sector, other carotenoids, e.g., β-apo-8′-carotinoic acid ethyl ester or canthaxanthin, are used as a dry powder to pigment the skin and egg yolk of poultry. Carotenoids identical to the naturally occurring substances are being increasingly used to pigment salmon and trout in fish farming.

About 400 t/a of carotenoids are synthesized (calculated as pure compounds). The price is between 800 and 2000 DM/kg (calculated on the basis of 100 % purity). Producers are Hoffmann LaRoche and BASF.

2.12. Tolerance

Excessive feeding of vitamin A compounds (single doses of ca. 2×10^6 I.U. or repeated administration of 0.2×10^6 I.U. and more to adults) causes severe damage (hypervitaminosis A). Typical signs in experimental animals are skeletal fractures and bleeding. The molecular cause for these symptoms is an increase in the membrane permeability in lysosomes with the release of proteolytic enzymes (cathepsin D) [201]. This is produced by vitamin A that is not bound to a carrier protein.

High doses of provitamin A compounds do not cause hypervitaminosis A.

3. Vitamin D

3.1. Introduction

The group of vitamins D (calciferols) are compounds which play a central role in the maintenance (homeostasis) of calcium and phosphorus concentration in the body fluids of vertebrates, including humans, by controlling intestinal calcium absorption and calcium mobilization of the bones. According to present knowledge, the vitamins D are biologically inert, and before they can fulfil their physiological role they must be converted by two subsequent enzymatic hydroxylations in the liver and the kidney to the biologically active vitamin D derivative.

A selection of reviews and books is given in general references [202–210]. An excellent overview of major developments in particular vitamin D research frontiers is offered by the *Proceedings of Vitamin D Workshops* which are organized every three years [211–213].

3.2. History

Rickets, a disease of sucklings and children, is a serious disorder in bone development due to a disturbed calcium and phosphorus metabolism as a consequence of vitamin D deficiency. Rickets became a serious health problem with industrialization in geographical areas of low-incident sunlight in northern Europe and North America, as well as with the accompanying advances in urbanization of society. A relation between exposure to sunlight and its preventive action towards rickets was already recognized in the early 1800s (Sniadecki). In 1919 Melanby succeeded in producing rickets experimentally in dogs and cured the disease by adding cod liver oil, a known popular remedy for the prevention of rickets, to their food. Shortly afterwards, Huldshinski demonstrated that exposure of rachitic children to sunlight or artificial UV light also cures the disease. Food and vegetable oils exposed to UV light exhibited the same therapeutic effect as cod liver oil. The component of the vegetable oil activated by UV light was identified as a chromophoric trace impurity accompanying the plant sterols in the nonsaponifiable fraction and inseparable from the parent sterol even by repeated crystallization. Analogous impurity was also detected in the crude animal sterol cholesterol. The absorption spectra of the impurities mentioned, resembled that of ergosterol, an already known

$\Delta^{5,7}$-sterol isolated from yeast. Indeed, ergosterol when irradiated yielded a mixture of products possessing high antirachitic activity, from which two independent teams (WEBSTER, WINDAUS) succeeded, in the early 1930s, in isolating the active principle: first in impure (vitamin D_1 or calciferol) and later in pure crystalline form, named it vitamin D_2 (ergocalciferol), and elucidated its structure by means of classical chemical degradation reactions (WINDAUS, HEILBRON). Vitamin D_3 (cholecalciferol), the active principle isolated from cod liver oil (BROCKMANN) was prepared by irradiation of 7-dehydrocholesterol (cholesta-5,7-diene-3β-ol), a synthetic analogue of ergosterol (and accompanying impurity of crude cholesterol), and its structure (WINDAUS, HEILBRON) was verified by total synthesis (INHOFFEN). Further vitamins D, products of irradiation of 7-dehydro derivatives of 22,23-dihydroergosterol (D_4), β-sitosterol (D_5), stigmasterol (D_6) and campesterol (D_7), were reported, the three last named possessing only low activity. The complex photochemistry was elucidated by HAVINGA and VELLUZ who recognized previtamin D as the key product of photolysis of steroidal 5,7-dienes (provitamins D) and as the intermediate of all subsequent transformations. HAVINGA corrected further the erroneous assumption of WINDAUS, who took vitamin D for the end product of the photolytic sequence, and identified it as a product of a thermal isomerization.

The years 1966 – 1971 brought a dramatic revival to the field of vitamin D due to the pioneer investigations of the three teams of DELUCA, KODICEK, and NORMAN. By using synthetic, labelled vitamin D_3 the named authors proved that in warmblooded animals it is converted by stepwise enzymatic hydroxylations and that one of the resulting metabolites, calcitriol (1α,25-dihydroxycholecalciferol) is the true highly active principle which performs all the functions ascribed previously to vitamin D_3. Calcitriol and other metabolites were isolated by means of advanced experimental techniques, and their structure was elucidated from their chemical and spectrometric properties and verified by synthesis. As under normal physiological conditions, humans and animals produce sufficient amounts of vitamin D_3 in the skin, the latter should not, strictly speaking, be classified as a vitamin, in contrast to vitamin D_2 which is available only from the diet. (A vitamin is a dietary component essential for health which the body is not able to synthesize.) However, the use of the designation vitamin D has been preserved as a general term for compounds exhibiting qualitatively the biological activity of calciferols and for terms such as vitamin D activity, vitamin D deficiency, etc. The name vitamin D_3 or vitamin D_2 is still used as a synonym for cholecalciferol or ergocalciferol, respectively. The active metabolite calcitriol, in view of its synthesis in the organism and its function, must, *per definitionem*, be classified as a hormone, and its precursor vitamin D_3 as a prohormone.

3.3. Structure and Nomenclature

The vitamins D belong chemically to the steroids [214] in which the B-ring of the steroid nucleus is cleaved between carbon atoms 9 and 10 (9,10-secosteroids). X-Ray analysis and NMR data [215–217] indicate that vitamin D_2 and D_3 and their derivatives exist in the crystal and predominantly in solution not as the cisoid, steroid-like form (**1a**, **1b**) – though according to computer calculations, this is the lowest energy conformation [218] – but as the coplanar conformer **2** (Fig. 1). (In **2** the A-ring is rotated through ca. 180° around the $C_6 - C_7$ linkage, giving a transoid diene system extending from C_5 to C_8.) In addition, **2** is an approximately equimolar mixture of two A-ring chair conformations [219, 220].

To avoid a certain confusion in the steroid nomenclature arising with the transoid conformation **2** for which the descriptors α and β do not apply, IUPAC [221] has recommended designating the chiral centres in the A-ring consequently as *R* and *S*. Nevertheless, systematic steroid nomenclature, as well as that of Chemical Abstracts, still use the traditional steroid notation derived from the cisoid form **1**. Thus vitamin D_3 (cholecalciferol, calciol) in IUPAC notation is (3*S*,5*Z*,7*E*)-9, 10-seco-5,7,10(19)-cholestatriene-3-ol (**2a**), and in systematic nomenclature (5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-3β-ol. Analogously, vitamin D_2 (ergocalciferol, ercalciol) (**2b**), which differs from vitamin D_3 in the side chain, is (3*S*,5*Z*,7*E*,22*E*)-9,10-seco-5,7,10(19),22-ergostatetraene-3-ol or

Figure 1. Structure of vitamin D_2 and D_3 and derivatives

(5*Z*,7*E*,22*E*)-9,10-secoergosta-5,7,10(19),22-tetraene-3β-ol. The abbreviated form of representation of the hydroxylated vitamin D metabolites such as 25-OH-D_3 for 25-hydroxycholecalciferol (**3a**) or 1,25-$(OH)_2$-D_3 for calcitriol (**4a**), though discouraged [221], is generally used throughout the literature. Subscript ciphers attached to trivial names (e.g., tachysterol$_3$ or lumisterol$_3$) correspond to that of the particular vitamin D.

3.4. Chemical and Physical Properties

The vitamins D, their metabolites, and analogues containing the characteristic 5,7,10(19)-triene system are highly unstable towards light, atmospheric oxygen, and acids; they are stable towards alkalies if protected from oxygen and light. Even in the crystalline state the vitamins D contain a certain amount of isomeric previtamin D with which they are in a temperature-dependent equilibrium. Preparations should therefore be kept protected from light and at low temperatures (+4°C or less) under inert gas. Heating to 180 °C leads to irreversible B-ring closure yielding pyro- and isopyrocalciferol (9α, 10α- or 9β,10β-cholesta-5,7-diene-3β-ol, respectively). Contrary to the provitamins (7-dehydrosterols), the vitamins D fail to give a precipitate with digitonin in ethanolic solution.

Vitamin D_3 (cholecalciferol, calciol) [*67-97-0*] (**2a**), $C_{27}H_{44}O$, M_r 384.6, colorless crystals, *mp* 84 – 85 °C (acetone), $[\alpha]_D$ +84° (acetone), UV (ethanol): λ_{max} 265 nm (ε 18 200) [222], NMR: [223], MS: [224], ^{13}C NMR: [223, 225].

Vitamin D_2 (ergocalciferol, ercalciol) [*50-14-6*] (**2b**), $C_{28}H_{44}O$, M_r 396.6, colorless prisms, *mp* 114.5 – 117 °C (acetone), $[\alpha]_D$ +102.5° (ethanol); UV (ethanol): λ_{max} 265 nm (ε 19 200) [222], NMR: [226], MS [227].

Previtamin D_3 [(6*Z*)-tacalciol], (3*S*,5*Z*,7*E*)-9,10-secocholesta-5 (10),6,8-triene-3-ol, (6*Z*)-9, 10-seco-5 (10),6,8-cholestatriene-3β-ol [*1173-13-3*] (**12a**), $C_{27}H_{44}O$, M_r 384.6, oily, UV (ethanol): λ_{max} 262 nm (ε 9000).

25-Hydroxycholecalciferol monohydrate (calcidiol, calcifediol), (3*S*,5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-3,25-diol, (5*Z*,7*E*)-9,10-seco-5,7,10(19)-cholestatriene-3β,25-diol [*19356-17-3*] (**3a**), $C_{27}H_{44}O_2 \cdot H_2O$, M_r 418.6, *mp* 81 – 83 °C (aq. acetone), $[\alpha]_D$ +77° (trichloromethane), UV (ethanol): λ_{max} 265 nm (ε 18 000), NMR: [228, 229], MS: [229], ^{13}C NMR: [225].

1α,25-Dihydroxycholecalciferol (calcitriol), (1*S*,3*R*,5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-1,3,25-triol, (5*Z*,7*E*)-9,10-seco-5,7,10(19)-cholestatriene-1α,3β,25-triol

[*32222-06-3*] (**4a**), $C_{27}H_{44}O_3$, M_r 416.6, white solid, *mp* 115 – 116 °C (methyl formate) [230], $[\alpha]_D$ +45° (ethanol), UV (ethanol): λ_{max} 265 nm (ε 16 600), IR: [231], NMR: [232], MS: [232], ^{13}C NMR: [225].

24*R*,25-Dihydroxycholecalciferol (secalciferol), (3*S*,24*R*,5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-3β,24,25-triol, (24*R*,5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-3β-24,25-triol [*55721-11-4*] (**5a**), $C_{27}H_{44}O_3$, M_r 416.6, white crystals, *mp* 136 – 137 °C (methyl formate), $[\alpha]_D$ +113° (ethanol), UV (ethanol): λ_{max} 265 nm, NMR: [233], MS: [234].

1α-Hydroxycholecalciferol (alfacalcidiol) (1*S*, 3*R*,5*Z*,7*E*)-9,10-secocholesta-5,7,10(19)-triene-1,3-diol, (5*Z*,7*E*)-9,10-seco-5,7,10(19)-cholestatriene-1α,3β-diol [*41294-56-8*] (**6a**), $C_{27}H_{44}O_2$, M_r 400.6, white crystals, *mp* 138 – 139.5 °C (methyl formate), $[\alpha]_D$ +29° (dioxane), UV (ethanol): λ_{max} 264 nm (ε 17 600), IR: [235], NMR: [235], MS: [235].

Calcipotriol (1*S*,3*R*,24*S*,5*Z*,7*E*,22*E*)-24-cyclopropyl-9,10-seco-5,7,10(19),22-cholatetraene-1,3,24-triol, (24*S*,5*Z*,7*E*,22*E*)-24-cyclopropyl-9,10-seco-5,7,10(19),22-cholatetraene-1α,3β,24-triol [*112965-21-6*] (**4c**), $C_{27}H_{40}O_3$, M_r 412.6, crystals, *mp* 166 – 168 °C (methyl formate), UV (ethanol): λ_{max} 264 nm (ε 17 200), NMR: [236], MS: [236].

3.5. Biosynthesis and Occurrence

3.5.1. Biosynthesis

The natural source of vitamin D_3 in warm-blooded animals and humans is the transformation of provitamin D_3 (7-dehydrocholesterol), a product of cholesterol biosynthesis, in the skin [210] when exposed to the ultraviolet component of sunlight (λ= 290 – 315 nm, UV-B radiation). The light penetrates into the epidermis and converts provitamin D_3 photochemically to previtamin D_3, and this isomerizes at body temperature to vitamin D_3. The photolysis is very efficient [206], though liable to seasonal and climatic variations. Pigmentation and aging significantly decrease the capacity of human skin to produce vitamin D_3.

The vitamin D_3 produced either endogenously or obtained dietarily enters the lymphatic system bound to the specific vitamin D binding protein (DBP) and is transferred first to the liver and hydroxylated there at C_{25} to the biologically inactive 25-hydroxycholecalciferol (calcifediol, 25-OH-D_3) (**3a**), the DBP-bound, major circulating form of vitamin D_3, and then transferred to the kidney, the site of further hydroxylation. Renal hydroxylation is strictly controlled by serum calcium level: a decrease below the physiological concentration (86 – 105 µg/mL) stimulates production of parathyroid hormone (parathormone, PTH) [237] in the parathyroid gland, which activates renal 25-OH-D_3-1α-hydroxylase. The enzyme converts 25-OH-D_3 into the 1α-hydroxylated highly active hormone calcitriol (**4a**), which carries out all the known functions ascribed to the vitamin D_3. The resulting normalization of calcium in serum suppresses PTH production, and calcitriol deactivates the 1α-hydroxylase by feed-back control. The deactivation is associated with the activation of renal 25-OH-D_3-24-hydroxylase, which starts to convert 25-OH-D_3 into 24*R*,25-dihydroxycholecalciferol [24*R*,25-$(OH)_2$-D_3] (**5a**). The physiological role of this metabolite, if any, is still the subject of controversial reports. Both metabolites are subjected to a complex catabolic process which proceeds via additional hydroxylations up to the final cleavage of the side chain [203, 206, 238]. Should calcium concentration rise above normal, the thyroid gland starts to secrete the hormone calcitonin (CT) [239], a counterregulator of PTH, which blocks mobilization of calcium from the bone and stimulates excretion of calcium in the kidney. Vitamin D_2 (**2b**), the source of which is the diet, is metabolized in mammals and humans analogously to vitamin D_3, to give 25-OH-D_2 (**3b**) and 1α, 25-$(OH)_2$-D_2 (**4b**).

3.5.2. Occurrence

Fish oils contain considerable amounts of vitamin D_3, accompanied by small amounts of vitamin D_2. Lesser concentrations of vitamin D_3 are found in egg yolk, mammalian and human breast milk (as sulfate), invertebrates, and mushrooms. Natural sources of vitamin D are summarized in [240]. Generally, vegetables and fruits

do not contain vitamin D. The glycoside of calcitriol was detected in the leaves of calcinogenic plants, e.g., *Solanum malacoxylon* [241]. The cutaneous photosynthesis of vitamin D_3 in fish is questionable because of the low transmittance of water for UV light. The mode of accumulation of large hepatic stores of vitamin D_3, the physiological significance of which is poorly understood, is most probably a result of concentration through food chains starting from zoo- and phytoplankton. Hypothetical, nonphotochemical enzymic mechanisms of vitamin D_3 synthesis in fish and some terrestrial subterranean or nocturnal herbivores have been discussed [242].

3.6. Vitamin D Requirements

The daily vitamin D requirements in human adults probably do not exceed 100 – 200 I.U. (1 mg = 40 000 I.U.); this can readily be obtained from the dietary sources (eggs, cheese, liver, oily fish) and exposure to sunlight. For children up to the age of six, the recommended allowance is 400 I.U./d; this dose may represent the upper limit of vitamin D required [203, 243]. Intake of vitamin D in excess of 1000 I.U. per day is potentially dangerous to normal children and adults and must be avoided. Vitamin D intoxication is believed to be the result of high circulating 25-OH-D_3 levels that, mimicking 1,25-$(OH)_2$-D_3 on the receptor, lead to dangerous hypercalcemia, which may result in irreversible soft tissue calcifications (kidney, lungs, heart, pancreas, aorta). Food is supplemented in many countries by vitamin D_3 or D_2 (milk, margarine); the daily portion of a certain food contains usually one third or one half of the total vitamin requirement and the vitamin amount in a definite portion of food is declared on the package. The vitaminized food products are subject to control by state institutions. In veterinary nutrition, food fortification with vitamin D is important for the normal development of young animals and for husbandry of cattle, swine, and poultry. The vitamin D requirements are given in I.U. either per animal or kilogram body weight and day or per kilogram dry food per day [244, 245]. It has, however, to be emphasized that the data related to requirement levels depend on a number of different factors and should be considered as guideline recommendations only and that generally valid data are not obtainable.

3.7. Pharmacological Effects and Uses

Calcitriol is a hormone which functions at the level of the target cell nucleus in a fashion analogous to that of steroid hormones. The actions of calcitriol are mediated by a specific 1,25-$(OH)_2$-D_3 receptor molecule which belongs to the superfamily of protein receptors for steroid hormones [246, 247]. The calcitriol – receptor complex is transported to the nucleus and stimulates the transcription of the gene coding for proteins that modify the functions of the target cell. Calcitriol exerts its main task, the control of calcium metabolism [248], on the classic target tissues, i.e., intenstine, bone, and kidney. As, however, specific 1,25-OH-D_3 receptor molecules have been identified in a series of other tissues as well, this indicates far broader calcitriol activities than formerly assumed. Some biological responses of calcitriol are generated by nongenomic pathways and two different forms of the receptors were postulated for genomic and nongenomic mechanisms [249]. The steroid-like cisoid conformation **1** is suggested to be responsible for the nongenomic function [249].

3.7.1. Calcium Homeostasis and Disorders of Calcium Metabolism

The most obvious effect of calcitriol is normal bone development by maintenance of plasma calcium and phosphorus concentrations at normal levels. This mechanism is carried out by activation of intestinal calcium and phosphorus absorption, improvement of renal calcium reabsorption, and stimulation of calcium mobilization from the bone. The most important indication in human medicine in this field is the prevention and healing of vitamin D deficiency in growing children (rickets) and in adults (osteomalacia). Patients suffering from renal failure and anephric patients on dialysis produce either insufficient amounts of calcitriol or fail to produce it at all, and as a result exhibit low intestinal calcium absorption, low plasma calcium concentration (hypocalcemia), and secondary hyperparathyroidism (overproduction of

PTH), the latter being the major factor in the development of renal osteodystrophy. Oral doses of calcitriol or its synthetic analogue 1α-hydroxycholecalciferol (**6a**) – 1α-OH-D_3, before it acts, is hydroxylated at C_{25} in the liver – normalize the hypocalcemia and the PTH concentration in the serum. The therapy requires medical surveillance and thorough control of serum calcium concentrations. Postmenopausal and age-related (senile) osteoporosis, the most frequent metabolic bone disease seen in medical practice, is a failure of calcium absorption which results in a shift from dietary sources to skeletal calcium mobilization accompanied by a continuous loss of bone substance. Clinical trials using calcitriol for treatment of postmenopausal women have been reported [250,251] but the application of calcitriol for treatment of senile osteoporosis is still the subject of controversy. Calcitriol has been reported to support increased egg production and egg shell breaking strength, and recommended for prevention and treatment of parturient paresis (milk fever), a hypocalcemic disorder of dairy cows. Substantial economic losses in farming have been caused by severe calcinoses of grazing animals after intake of leaves of calcinogenic plants containg calcitriol in glycosidic form [241]. Vitamin D_2 and 1α,25-$(OH)_2$-D_2 are approximately equally as active in humans and mammals as the corresponding vitamin D_3 derivatives but are substantially less active in avian species; the discrimination is due to the vitamin D transport protein, which has low affinity towards vitamin D_2 derivatives [252].

3.7.2. Further Activities

Nuclear 1,25-$(OH)_2$-D_3 receptors have been demonstrated in tissues not primarily related to mineral homeostasis, such as the skin, parathyroid cells, pancreas, heart muscle, placenta, and others. Further, a substantial fraction of all malignant cells contain significant amounts of the receptor. Calcitriol has been shown to influence the proliferation and differentiation of several tissues and may also have immunoregulatory properties [253]. Calcitriol-receptor complex suppresses the gene of the PTH in the parathyroid gland [254], stimulates insulin secretion in the pancreas [255,256], inhibits leukemic cell growth and is an effective antiproliferative agent with potential use in cancer therapy [257]. Similar effects have been demonstrated on human epidermal cells, where calcitriol inhibits proliferation and induces terminal differentiation of keratinocytes; this has been used for treatment of psoriasis (hyperproliferation epidermal disorder). The antiproliferative and differentiation inducing effects of calcitriol are dose dependent and require supraphysiologic doses. The obvious clinical limitation, the potentially serious hypercalcemic side effect of doses higher than a few micrograms per day, questions a long-term therapeutic use and calls for analogues having diminished calcemic activity. Analogues have been synthesized that possess high proliferation/differentiation activity combined with a significantly lower calcemic effect [236,258] and the structure – function relationship has been discussed [259]. Two synthetic derivatives, calcipotriol (**4c**) and tacalcitol [(5*Z*,7*E*,24*R*)-9,10-secocholesta-5,7,10(19)-triene-1α,3β,24-triol], have been introduced to the market for topical treatment of psoriasis.

3.8. Synthesis

3.8.1. Synthesis of Vitamin D_3 and D_2

On an industrial scale, the vitamins D_3 are manufactured by chemical synthesis only. The fish oils, the natural source of vitamin D_3, are only used for preparation of vitamin concentrates. Starting materials for vitamins D are 7-dehydrosterols ($\Delta^{5,7}$-sterols). Vitamin D_2 (**2b**) is prepared from the natural substance ergosterol (**11b**); its synthetic analogue, 7-dehydrocholesterol (**11a**) is the starting material for vitamin D_3 (**2a**).

The synthesis of 7-dehydrocholesterol (Fig. 2) starts from commercially available cholesterol (**7a**), the hydroxy group of which is protected as acetate or benzoate (**8a**). Allylic bromination to the 7-bromo derivative (**9a**) and dehydrobromination to the $\Delta^{5,7}$ ester (**10a**) followed by saponification gives the free 7-dehydrocholesterol (**11a**).

The photolysis of the 5,7-diene system of either 7-dehydrocholesterol (**11a**) or ergosterol (**11b**) (for details see → Photochemistry, Chap. 5.2.) is carried out by irradiation with ultraviolet light of a mercury lamp in an inert sol-

Figure 2. Synthesis of vitamin D_3 and D_2
Ac = CH_3CO, Bz = C_6H_5CO
a, **b**: R^1 see Figure 1

vent [260] yielding previtamin D ((**12a**), (**12b**)) by reversible fission of the cyclohexadiene system in the B-ring between C_9 and C_{10}. The previtamin D is in an equilibrium with its ring reclosure photoproducts – the starting diene ((**11a**), (**11b**)) and its $9\beta,10\alpha$-isomer lumisterol ((**13a**), (**13b**)) – and with the product of *E*/*Z* photoisomerization of the 6,7 double bond, tachysterol ((**14a**), (**14b**)). The ratio of products and the predominating component in the reaction

mixture depends on the wavelength of the UV light used [261]. To avoid the slow, irreversible formation of over-irradiation products, photolysis is discontinued after max. 40 % turnover of the starting diene. The subsequent step, the thermal isomerization of previtamin D into vitamin D (**12a**, **12b** → **2a**, **2b**), is a reversible sigmatropic 1,7-hydrogen shift from C_{19} to C_9, performed by heating the solution of the photoproducts at 80 °C to a vitamin – previtamin equilibrium (ratio ca. 4 : 1). The reaction solution is then concentrated and treated with methanol to recover the sparingly soluble starting $\Delta^{5,7}$-diene. Tachysterol is removed as a Diels – Alder adduct with maleic anhydride. The resulting solution is evaporated to give crude vitamin D (vitamin D resin) which either is used directly for veterinary purposes or purified to crystalline vitamin D_3 or D_2 via an ester that crystallizes well [262] (3,5-dinitrobenzoate or butanoate), subsequent saponification, and final crystallization.

The introduction of triplet sensitizers that influence the *E*/*Z* isomerization of the 6,7 double bond by reconverting the undesirable side product tachysterol to previtamin (**14** →**12**), brought decisive progress in the photochemical transformation of 7-dehydrosterols and a very efficient optimization of the previtamin D yield. In practice, the 5,7-diene is irradiated as above, then the sensitizer is added and irradiation is continued to transform the tachysterol almost quantitatively to previtamin (double irradiation technique) [263].

3.8.2. Synthesis of Calcitriol

The classical pathway starts with the synthesis of 25-hydroxycholesterol (**15**) from an appropriate steroid derivative by degradation and resynthesis of the side-chain [238, 264, 265]. The method of choice for introduction of the 1α-hydroxy group in the A-ring of 25-hydroxy-cholesterol (**15**) is the three-step procedure of Barton (**15** → **16** → **17** → **20**) [266] which in a modified form [267] was applied for the industrial production of 1α,25-dihydroxycholesterol (**20**) (Fig. 3). The chemical introduction of the 1α-hydroxyl group was replaced later by an economic and for industrial purpose adapted [268] fermentative one-step 1α-hydroxylation [269] using dehydroepiandrosterone (**18**), a commercially available compound prepared by microbiological degradation of cheap plant sterols, as starting material. The synthesis of the side chain in the 1α-androstane derivative **19** gives 1α,25-dihydroxycholesterol (**20**) [270], followed by the conversion to calcitriol analogous to the synthesis of vitamin D (Fig. 2) using the double-irradiation technique [271]. Calcitriol is isolated by preparative HPLC and crystallized. The strategy of both the above-mentioned synthetic pathways is based on multistep manipulations of intact steroid ring systems, and the final conversion of the resultingly expensive 1α,25-dihydroxycholesterol to the seco-triene system via the 5,7-diene is realized by a sequence of reactions notorious for their moderate yields. A conceptually new alternative is the synthesis starting from the commercially available bulk product ergocalciferol (vitamin D_2) (**2b**) [228]. The pathway (Fig. 4) involves protection of the triene system as sulfur dioxide adduct **21**, cleavage and resynthesis of the side chain and chemical introduction of the 1α-hydroxy group (**23** → **29**) [228]. An alternative synthesis of calcitriol [230, 272] and calcipotriol [236] is based on a similar strategy. A promising approach, the direct fermentative 1α- and 25-hydroxylation of vitamin D_3 to calcitriol [273] has been reported. The total synthesis of calcitriol or other vitamin D metabolites and analogues [264, 274] has not yet been realized on an industrial scale.

3.9. Assays for Vitamin D and Metabolites

Assays for vitamin D and metabolites have been reviewed [275]. The official method for determination of vitamin D in feedstuffs, tissues, and body fluids in the years 1922 – 1958 was the rat line test, a bioassay based on curative and preventive effects in rachitic or normal animals, kept on a rachitogenic diet containing varying amounts of vitamin D. The measure of healing of the rickets induced was evaluated after silver-nitrate staining of the split tibias. The method is sensitive (25 µg vitamin D_2 or D_3) but time consuming (7 – 14 d assay period) and nonspecific. An alternative to the line test, a subsequently adopted chemical method, is based on spectrometric estimation of the red coloration of vitamin D with antimony trichloride at 500 nm. The

1) SO_2 (liquid); 2) Et_3SiCl, imidazole, CH_2Cl_2; 3) $O_3/NaBH_4$, 4) TsCl, pyridine; 5) $NaHCO_3$, EtOH; 6) SeO_2, N-methylmorpholine N-oxide, CH_2Cl_2/MeOH; 7) $h\nu$, anthracene; 8) $BrMgCH_2CH_2C(CH_3)OTES$, Cu(I), THF; 9) Bu_4NF, THF

method was designed for estimations in pharmaceutical preparations containing larger quantities of vitamin D (> 250 µg) [276]. Official methods for vitamin D estimation are described in detail in [277].

Given the knowledge of vitamin Dmetabolism and the low concentrations of the metabolites in the plasma or serum (25-OH-D_3: 30 ng/mL, 1,25-$(OH)_2$-D_3: 30 – 40 pg/mL, 24,25-$(OH)_2$-D_3: 0.5 –2.0 ng/mL), two approaches were developed for the measurement of metabolites in plasma and tissues in vitro using ^{3}H-radiolabeled vitamin D derivatives: competitive protein-binding analysis (CPB) and radioimmunoassay (RIA). The CPB technique takes advantage of the high affinity for vitamin D metabolites of proteins occurring in serum (vitamin D-binding protein) or in intestinal target cells (cytoreceptors). For RIA, the vitamin D metabolites being themselves not antigenic, must be chemically modified to haptens which are then covalently linked to a protein molecule [mostly bovine serum albumin (BSA)]. The vitamin D derivative – BSA complex then constitutes the antigen which, injected into an animal, induces antibody formation. Both assays involve competition between a radiolabeled metabolite and the vitamin D derivative of interest for available sites on the binding protein. However, the low specificity of both the binding protein and the antibody and, furthermore, the presence of interfering substances in serum make prepurification and separation of the metabolites by extraction and chromatographic techniques indispensable. Significant advance in the isolation techniques has been the introduction of solid-phase extraction and "phase-switching" [278, 279]. The introduction of high performance liquid chromatography (HPLC) rendered separation and isolation of individual metabolites possible either for the assays mentioned above or for the direct measurement of HPLC peak areas using UV detection (for vitamin D and 25-OH-D only) or the highly sensitive fluorometric assay [280]. A combination of gas chromatography and mass spectrometry (GC – MS) [279] has also been introduced in this field. The accuracy and precision of differentassays for vitamin D and metabolites have been compared and discussed [281].

3.10. Trade Names and Economic Aspects

The pharmaceutical industry offers vitamin D_3, and to a lesser extent vitamin D_2, in pure crystalline form or as a solution in vegetable oil (1 000 000 I.U./g) for preparation of pharmaceuticals and for food supplementation. The majority of vitamin D_3 produced is the crude product, so-called vitamin D_3 resin, an intermediate for manufacturing dispersions in plant protein and dextrin matrix (about 500 000 I.U./g) used for fortification of animal feeds. Vitamin D_2 and D_3 are available in numerous drug products [282], in multivitamin specialities, and in fish oil concentrates. The main bulk producers of vitamin D are Solvay-Duphar (The Netherlands, D_3, D_2), Hoffmann-La Roche (Switzerland, D_3), BASF (Germany, D_3), Synthesia (Czech Republic, D_2). Annual worldwide vitamin D_3 production amounts to ca. 1.5×10^{15} I.U.; the production of calcitriol, the daily dose of which is 0.25 µg only, does not exceed several hundreds of grams. Trade names and the producers of synthetic metabolites and analogues [282] are summarized in Table 11. Commercially available tritiated derivatives for assays are available from Amersham (United Kingdom) and New England Nuclear Corp. (United States).

4. Vitamin E (Tocopherols, Tocotrienols)

4.1. Introduction

The eight naturally occurring substances with vitamin E activity are all derivatives of 6-chromanol. They belong to two groups of compounds. The first group (**1a**–**1d**) is derived from tocol (**1** with $R^1 = R^2 = R^3 = H$), a substance which has a saturated C_{16} isoprenoid side chain and has not yet been found in nature.

The second group (**2a**–**2d**) consists of derivatives of tocotrienol, which has a triply unsaturated C_{16} side chain (at position 3′, 7′, and 11′). The same α, β, γ, and δ structures are found as in the tocopherol group (**1a**–**1d**).

Table 11. Trade names and producers of synthetic vitamin D metabolites and analogues

Abbreviation	Generic Name	Trade Name	Producer
25-OH-D_3	calcifediol	Dedrogyl	Roussel-Uclaf (France)
		Calderol	Upjohn (United States)
		Hidroferol	Juventus (Spain)
25-OH-5E-D_3	5,6-*trans*-25-hydroxy-cholecalciferol	Delakmin	Roussel-Uclaf (France)
1α,25-$(OH)_2$-D_3	calcitriol	Rocaltrol	Hoffmann-La Roche (Switzerland, United States)
		Calcijex	Abbott (United States)
1α-OH-D_3	alfacalcidiol	Alfarol	Chugai (Japan)
		Dediol	Leo (Denmark)
		Eenalfadrie	Teva (Israel)
		Einsalpha	Thomae (Germany)
		Odinal	Hemofarm (Former Yugoslavia)
		OneAlpha	Leo (Denmark)
		Vetalpha	Crown Chem. (United Kingdom)
	calcipotriol	Daivonex	Leo (Denmark)
		Dovonex	Leo (United Kingdom)
1α,24R-$(OH)_2$-D_3	tacalcitol	Bonealfa Oint.	Teijin (Japan)
	dihydrotachysterol	A.T. 10	Bayer (Germany)
		Calcamin	Wander (Switzerland)
		DHT	Roxane (United States)
		Dihydral	Duphar (Belgium)
		Dygratyl	Ferrosan (Denmark)
		Hytakerol	Sterling (United States)
		Tachyrol	Duphar (Denmark)
		Tachystin	Ankerwerk (Germany)

1a, α-Tocopherol: $R^1 = R^2 = R^3 = CH_3$
1b, β-Tocopherol [*148-03-8*]: $R^1 = R^3 = CH_3$, $R^2 = H$
1c, γ-Tocopherol [*54-28-4*]: $R^1 = H$, $R^2 = R^3 = CH_3$
1d, δ-Tocopherol [*119-13-1*]: $R^1 = R^2 = H$, $R^3 = CH_3$

2a, α-Tocotrienol [*1721-51-3*]: $R^1 = R^2 = R^3 = CH_3$
2b, β-Tocotrienol [*490-23-3*]: $R^1 = R^3 = CH_3$, $R^2 = H$
2c, γ-Tocotrienol [*14101-61-2*]: $R^1 = H$, $R^2 = R^3 = CH_3$
2d, δ-Tocotrienol [*25612-59-3*]: $R^1 = R^2 = H$, $R^3 = CH_3$

Of the above eight compounds, α-tocopherol (**1a**), 2,5,7,8-tetramethyl-2-(4′,8′,12′-trimethyltridecyl)-6-chromanol, has the highest biological vitamin E activity and, therefore, the greatest industrial and economic importance. It is the predominant tocopherol in human and animal tissue.

The tocopherols (**1**) have three chiral centers, at positions 2, 4′, and 8′. Until now, only tocopherols having the R configuration at all three chiral centers have been found in nature.

(2*R*,4′*R*,8′*R*)-α-tocopherol (**1a**)

The correct denomination for naturally occurring α-tocopherol (**1a**) is (2*R*,4′*R*,8′*R*)-α-tocopherol [*59-02-9*] or briefly (*R,R,R*)-α-tocopherol. Totally synthetic α-tocopherol, which is racemic with respect to each stereocenter, should be denominated (2*RS*,4′*RS*,8′*RS*)-α-tocopherol [*10191-41-0*], or briefly (all-*rac*)-α-tocopherol. The denominations *d*- and *dl*-α-tocopherol, which have been used frequently for the (*R,R,R*)-enantiomer and the mixture of all eight stereoisomers, respectively, should not be used anymore.

The tocotrienols (**2**) have the (2*R*,3′*E*,7′*E*) configuration.

4.2. History

While studying the connection between fertility and nutrition, EVANS and BISHOP discovered in 1922 [291] that the absence of a substance in the diet of female rats led to death of the fetus and its resorption. This substance was first designated Factor X and later vitamin E [292]. In the 1920s and 1930s, it was observed that apart from the damage done to the reproductive system in male and female rats, a diet in which vitamin E had been oxidatively destroyed by iron(III) chloride produced encephalomalacia in chickens and muscular dystrophy in guinea pigs and rabbits [293–295].

In 1936, EVANS isolated from wheat-germ oil an alcohol which was given the name α-tocopherol (Greek: *tokos*, childbirth; *phero*, to bear) [296].

In 1937, two additional substances were isolated via crystallized allophanates and named β- and γ-tocopherol; they have lower biological activity than α-tocopherol [297]. δ-Tocopherol was discovered later [298].

In 1938, FERNHOLZ elucidated the structure of α-tocopherol based on the results of pyrolytic and oxidative degradation [299]. In the same year, KARRER et al. succeeded in synthesizing α-tocopherol from trimethylhydroquinone and phytyl bromide [300].

The structures of α-, β-, γ-, and δ-tocotrienol were elucidated in the 1960s [301]. The first synthesis of the tocotrienols was achieved by ISLER et al. in 1963 [302]. This was followed in 1976 by the synthesis of α-tocotrienol in the natural 2*R* form [303].

4.3. Physical Properties

The melting point of natural α-tocopherol lies between 2.5 and 3.5 °C and that of γ-tocopherol between −3 and −2 °C [304]. The melting points of various esters, e.g., acetate [305], allophanate [297], *p*-phenylazobenzoate [306], *p*-nitrophenylurethane [297], and 2,4-dinitrobenzoate [300], can be used to determine the purity.

The optical rotation of the natural tocopherols is very small and solvent dependent. The specific optical rotations $[\alpha]^{25}_{546}$ of some stereoisomeric α-tocopherols and their derivatives are listed in Table 12 and those of the natural tocopherols are given in the following:

α-Tocopherol	+0.32 (ethanol)	−3.0 (benzene)
β-Tocopherol	+2.9 (ethanol)	+0.9 (benzene)
γ-Tocopherol	+2.2 (ethanol)	−2.4 (benzene)
δ-Tocopherol	+3.4 (ethanol)	+1.1 (benzene)

Tocopherols are light yellow viscous oils at room temperature. They are readily soluble in lipophilic solvents and ethanol, but practically insoluble in water.

The UV spectra of the tocopherols and tocotrienols in ethanol have a maximum at 292–298 nm (α-tocopherol: 292 nm). Acetylation of the phenolic hydroxyl group shifts this maximum to 276–285 nm (α-tocopherol acetate: 284 nm) [309].

Nuclear resonance spectroscopy [283,312, 313], IR spectroscopy [310,311], and mass spectroscopy [314,315] are used to differentiate differently substituted tocopherols and tocotrienols.

4.4. Chemical Properties

The tocopherols (**1**) are gradually oxidized by atmospheric oxygen, producing a reddish color. In the absence of oxygen, they are resistant to alkali and heat up to 200 °C, and can be vacuum distilled without decomposition.

Tocopherol esters are resistant to atmospheric oxygen at ambient temperature.

Other chemical properties of the tocopherols are determined by:

1) The free phenolic hydroxyl group, which can be esterified [316] or etherified
2) A free position in the aromatic ring (except in α-tocopherol and α-tocotrienol) which is available for hydroxymethylation, chloromethylation, nitrosation, diazotization, etc.
3) Ready oxidizability (as the monoether of a hydroquinone) [317]

Tocopherol exerts an antioxidative effect, terminating radical chain reactions. This is due to the ready release of a hydrogen atom with the formation of the relatively inert tocopheroxy radical [318–320]. Tocopherol can be regenerated from the tocopheroxy radical in vivo by ascorbate or coenzyme Q10–hydroquinone [319,320]. More recent studies show that α-tocopherol is a much more potent antioxidant

Table 12. Specific optical rotation of stereoisomeric α-tocopherols [284, 306, 308]

Stereoisomer	Free α-tocopherol, $[\alpha]_D^{25}$ (ethanol)	*p*-Phenylazobenzoate, $[\alpha]_{600}^{25}$ ($CHCl_3$)	Prod. of oxidation with $K_3Fe(CN)_6$, $[\alpha]_D^{25}$ (isooctane)	Acetate, $[\alpha]_D^{25}$ (ethanol) [307]
2*R*,4′*R*,8′*R*	+0.75°	+7.07°	+26°	+3.3°
2*RS*,4′*R*,8′*R*	+0.38°	0°	0°	
2*S*,4′*R*,8′*R*	+0.19°	−7.64°	−25.8°	−2.1°
2*R*,4′*RS*,8′*RS*		+6.96°	+25.8°	+1.9°
2*S*,4′*RS*,8′*RS*	−0.14°	−7.47°	−23.6°	

than γ-tocopherol and the other homologues with a lower degree of methylation [321].

4.5. Metabolism and Importance in the Organism

Vitamin E is the most important lipid-soluble biological anitoxidant [322]. It is localized in cellular and subcellular membranes which are rich in polyene fatty acids. Since it reacts with free radicals faster than polyene fatty acids, it interrupts the chain reaction of lipid oxidation. Therefore, vitamin E is essential for the morphological integrity and functionality of the membranes of all cells [323].

The antioxidative effect in vitro is not identical with the biological activity: γ-tocopherol has about half the antioxidative effect of α-tocopherol but only about one-tenth of its biological activity [324]. This discrepancy appears to be due to differences in the lipoprotein-bound transport of tocopherols in the plasma.

In the course of fat digestion, vitamin E is absorbed in the small intestine [286, 325]. Bile acids and pancreatic lipase are required for absorption. In the case of malabsorption of lipids, the risk of vitamin E deficiency exists. Transport from the intestine to the systemic circulation proceeds via the chylomicrons of the lymph. Vitamin E is transported in the plasma bound to lipoproteins (mainly low density lipoproteins, LDL) [324]. The normal plasma level is 10 µg/mL.

The functions of vitamin E are revealed by the pathological results of its deficiency (see Section 4.6) [286]. Epidemiological studies on humans have shown that a high vitamin E intake is associated with a lower risk of atherosclerosis and coronary heart disease [326]. Prophylactically, vitamin E appears to be of importance in cell ageing, in diseases caused by the involvement of free radicals (e.g., ventricle bleeding in premature infants, senile cataract, coronary heart disease, and other ischemic reperfusion damage), and in cancer of various organs [327, 328]. Vitamin E stimulates cellular and humoral immunity [329].

Vitamin E is practically nontoxic, excess vitamin being eliminated via the bile.

4.6. Deficiency, Requirement, and Application

Vitamin E deficiency can occur due to an inadequate supply of the vitamin and lipid malabsorption. A lack of selenium and a high intake of polyene fatty acids enhance this deficiency. In animals, vitamin E deficiencies mainly affect the muscles, nervous system, cardiovascular system, formation of blood, and reproduction:

1) Muscles: The most frequent and economically most important manifestation of vitamin E deficiency in farm animals is degeneration of skeletal muscles ("white muscle disease," nutritional muscular dystrophy). As a rule, newborn and young animals (young chicks, lambs, piglets, calves, foals) are affected because their vitamin E supplies are low. Adequate vitamin E supply to the dam prevents this condition, and a combined injection of vitamin E and selenium is therapeutically effective.
2) Nervous system: In young chicks vitamin E deficiency leads to encephalomalacia, a fatal disease of the cerebellum which is caused by edema and necrosis.
3) Reproduction: In the female rat, vitamin E deficiency results in fetal death and resorption of the fetus. The classical biotest for the determination of the activity of vitamin E preparations is based on this manifestation. In the male, testicular function is disturbed

by irreversible degeneration of the germ cells (rat, rabbit, dog, monkey, pig).

4) Cardiovascular system: Piglets develop mulberry heart disease, an acute and usually fatal cardiomyopathy.

Clinical vitamin E deficiency in humans is rare [324]. This disease is usually associated with prolonged deficiency and lipid malabsorption. In rare cases, an inborn deficiency of plasma lipoproteins (abetalipoproteinemia) is the cause [324]. Neurological disorders such as cerebellar ataxia, a disturbed sense of position, loss of reflexes, and loss of the sensation of vibration are the main symptoms. They are caused by degenerative changes in the large motoneuron axons and in the myelin sheath [330].

In animal feeding, the following vitamin E additions are recommended (per animal and day): dairy cows 200 mg, young cattle 40–70 mg, beef cows 60–100 mg, and horses 600 mg.

The following additions are recommended per kilogram of complete feed: laying hens 20 mg, growing/finishing broilers 40 mg, turkeys 45 mg, piglets 45 mg, growing/finishing pigs 30 mg.

The recommended supply of vitamin E in the human diet in Germany is listed in Table 13.

Table 13. Recommended levels of vitamin E in the diet in milligrams tocopherol equivalent ∗ per day as stipulated by the Deutsche Gesellschaft für Ernährung (German Society for Nutrition) 1985

	RDI
Infants up to 2 months	3
Infants 3 to 11 months	4
Children, 1 to 3 years	5
Children, 4 to 6 years	7
Children, 7 to 9 years	8
Children, 10 to 12 years	10
Adolescents (15 years up)	12
Adults, 19 to 65 years	12
Pregnant women	14
Nursing mothers	17

∗ 1 mg (*R,R,R*)-α-tocopherol equivalent = 1.1 mg (*R,R,R*)-α-tocopheryl acetate = 1.49 mg (all-*rac*)-α-tocopheryl acetate = 2.0 mg (*R,R,R*)-β-tocopherol = 4 mg (*R,R,R*)-γ-tocopherol = 1.49 I.U.

4.7. Analysis and Standardization

Determination. Apart from photometric methods, chromatographic methods are primarily employed for analysis of vitamin E today.

An older method used to determine vitamin E in biological material is the Emmerie–Engel reaction, which is based on the colorimetric measurement of colored Fe(II) complexes with bipyridine [331] or 4,7-diphenyl-1,10-phenanthroline [332]. Spectrofluorometry is a very sensitive analytical method for free and esterified tocopherols. For instance, this method is used for vitamin E determinations in the spinal cord and in erythrocytes [333]. Photometric determination of tocopherol with the 2,2-diphenyl-1-picrylhydrazyl radical is also possible [334].

Of the chromatographic methods, gas chromatography (GC) and high performance liquid chromatography (HPLC) allow the most accurate determinations [335]. HPLC permits the simultaneous determination of vitamin E homologues [336], even directly in plasma and tissue samples [337].

The measurement of the optical rotation of $K_3Fe(CN)_6$ oxidation products can be used to differentiate the individual stereoisomers of α-tocopherol (see Table 12). However, only the configuration at C-2 can be determined with reasonable reliability. The diastereomers can be differentiated by gas chromatography [338] and ^{13}C NMR spectroscopy [339]. All eight stereoisomers of (all-*rac*)-α-tocopherol can be separated by using a combination of chiral HPLC and GC [340].

Standardization of Biological Activity. The relative biological activity of vitamin E is expressed in International Units (I.U.), 1 I.U. corresponding to the activity of 1 mg of racemic (2*RS*,4′*RS*,8′*RS*)-α-tocopherol acetate [*7695-91-2*]. The relative biological activities were mainly derived from fetus resorption tests on rats. They have been established by the National Formulary as follows [341]:

1 mg (2*RS*,4′*RS*,8′*RS*)-α-tocopherol acetate = 1.00 I.U.
1 mg (2*RS*,4′*RS*,8′*RS*)-α-tocopherol = 1.10 I.U.
1 mg (2*R*,4′*R*,8′*R*)-α-tocopherol acetate = 1.36 I.U.
1 mg (2*R*,4′*R*,8′*R*)-α-tocopherol = 1.49 I.U.

According to [342], 2*R*,4′*R*,8′*R*-α-tocopherol has a higher biological activity than that established by the National Formulary. As far as farm animals and humans are concerned,

the biological activity of the different forms of vitamin E is a controversial subject.

The relative biological activity of the eight α-tocopherol stereoisomers, determined by fetus resorption tests in rats [343] is as follows:

2*R*,4′*R*,8′*R*	100
2*R*,4′*R*,8′*S*	90
2*R*,4′*S*,8′*S*	73
2*R*,4′*S*,8′*R*	57
2*S*,4′*S*,8′*S*	60
2*S*,4′*R*,8′*R*	31
2*S*,4′*S*,8′*R*	21
2*S*,4′*R*,8′*S*	37

The *R* configuration at C-2 of the chromane ring seems to be important for high biological activity.

Biotests. Data on the relative biological activities of the tocopherol stereoisomers are obtained in animal experiments. The biological activity is determined by the ability of the test substances to prevent or remedy symptoms of vitamin E deficiency in comparison with a standard substance. The following test systems (bioassays) are preferentially used:

1) The fetus resorption test [344] in pregnant rats with vitamin E deficiency is the classical method for the determination of the biological activity of tocopherols.
2) The erythrocyte hemolysis test in the rat [345] is an in vitro process which measures the protective function of vitamin E against peroxide-induced hemolysis of erythrocytes. This test is also applied to humans [346].
3) In the muscular dystrophy test in the rat, rabbit, and chicken, muscular damage due to vitamin E deficiency is measured either directly [347] or via the determination of enzyme activities, e.g., plasma pyruvate kinase activity [348] as a measure of the course of muscular dystrophy.

4.8. Occurrence

All eight tocopherol (**1a**–**1d**) and tocotrienol homologues (**2a**–**2d**) occur in nature. Appreciable amounts are contained, above all, in plant oils. The highest concentration by far is found in wheat germ oil (ca. 0.2 %) [349]. Considerable amounts are also contained in soybean, sunflower, rape, corn, and peanut oil.

A survey of the total concentration of tocopherols in foods (in milligrams per 100 g) is provided in the following:

Wheat germ oil	215.4
Soybean oil	14.6
Sunflower oil	55.8
Peanut oil	17.2
Olive oil	12.0
Cocoa butter	1.0
Coconut fat	0.8
Pollard	2.4
Corn	2.0
Wheat	1.4
Barley	0.2
Oats	1.5
Soybeans	1.2
Beans (white)	2.1
Asparagus	1.5
Tomatoes	0.9
Carrots	0.6
Beans (green)	0.3
Garlic	0.1
Cauliflower	0.1
Walnut	20.0
Hazelnut	26.0
Peanut	9.0
Chestnut	1.2
Coconut	1.0

The concentrations of vitamin E in animal foods are much lower than those in plant products. The concentration is subject to major fluctuations caused by the seasonal concentration variations in green forage plants.

The concentration of various tocopherol and tocotrienol isomers in foods and the effect of processing and storage on the tocopherol content are described in [350].

4.9. Economic Aspects

Animal feeds represent the most important market for vitamin E. Of the world production, ca. 75 % is added to industrially produced feed mix for animals. The main product is a 50 % adsorbate of tocopherol acetate on silica gel. Formulations dispersible in cold water also exist.

The pharmaceutical, food, and cosmetic sectors account for ca. 25 % of world consumption. Special formulations are used here, e.g., spray formulated dry powders or adsorbates. The compound mainly used in the encapsulation of vitamin E is 98 % (all-*rac*)-α-tocopherol acetate. (All-*rac*)-α-tocopherol is also employed to prevent oxidation processes in oils and fats.

While totally synthetic (all-*rac*)-α-tocopherol is represented in all areas of application, the use of semisynthetic (*R,R,R*)-α-tocopherol from natural sources is almost exclusively restricted to the pharmaceutical, food, and cosmetic industries.

The most important producers of (all-*rac*)-α-tocopherol acetate are Hoffmann-La Roche (Switzerland) which has plants in Switzerland and the United States, and BASF (Germany), with plants in Germany and the United States. Other producers are Rhône-Poulenc (France) and Eisai (Japan). Vitamin E from natural sources is produced by ADM and Henkel in the United States. Smaller amounts are also produced in Japan.

In 1994, ca. 20 000 t of synthetic vitamin E and ca. 2000 t of vitamin E from natural sources (calculated as 100 % product) were consumed by the world market. Regions of high demand are the United States and Western Europe. Owing to consumer habits, demand in the human sector in the United States is more pronounced than in other regions of the world.

4.10. Biosynthesis

Tocopherols are synthesized by higher plants and algae. The precursor of the aromatic nucleus of the tocopherols is shikimic acid (**3**) which is converted to homogentisic acid (**4**) [351]. This synthesis can proceed in plants, algae, and bacteria, but not in the animal organism.

Starting with homogentisic acid (**4**), there are two pathways for the biogenesis of vitamin E (Scheme 10).

In the "tocopherol pathway," [352] homogentisic acid (**4**) reacts with phytyl pyrophosphate with elimination of CO_2 to give the intermediate **6** [353]. The "tocotrienol pathway" starts with the condensation of homogentisic acid (**4**) with geranylgeranyl pyrophosphate to give the intermediate **5**. Enzymatic cyclization of **5** or **6** yields δ-tocotrienol or δ-tocopherol, respectively. Some of the enzymes involved in these synthetic pathways have been isolated [354].

The *S*-methyl group of *S*-adenosylmethionine methylates δ-tocotrienol to give β-, γ-, and α-tocotrienol, and δ-tocopherol to give the corresponding tocopherols [355]. In some organisms, the second methyl group in the aromatic ring is introduced before cyclization. The enzyme responsible for subsequent cyclization to γ-tocopherol has been isolated from algae [356], and the cyclization mechanism elucidated [357].

The hydrogen source for the conversion of tocotrienols to the corresponding tocopherols is NADPH [358].

4.11. Production

4.11.1. Semisynthetic Vitamin E: Isolation from Plant Oils and Methylation

The most important natural sources of vitamin E are plant oils and fats. The deodorization of edible oils [359] yields as a byproduct deodorizer sludges which contain tocopherols in economically interesting concentrations (3–15 %) [360]. The deodorizer sludge from alkaline chemical refining of soybean oil, for instance, contains ca. 10 % of tocopherols, 10–20 % of free sterols and their fatty acid esters, 40–50 % of free fatty acids, triglycerides, and hydrocarbons (e.g., squalene).

Various processes are available for the purification of tocopherols. The fatty acids can be extracted [361] and separated in the form of sparingly soluble calcium salts [362]. Alternatively, they can be eliminated by distillation, preferably after esterification [363]. The sterols

can be separated by treatment with hydrogen chloride [364] or $CaCl_2$ [365], by crystallization [361, 366], or by extraction [367]. Alternatively, the free sterols can be esterified with the excess fatty acids, and the tocopherols can be separated from the high-boiling sterol fatty acid esters by distillation [368].

After removal of the free fatty acids, the tocopherols can be concentrated by adsorption on basic ion exchangers.

The amount of α-tocopherol and, consequently, the specific vitamin E activity in the mixture of tocopherols isolated from soybean oil are low (high proportion of δ- and γ-tocopherol).

To improve the natural mixed tocopherols, methyl groups are substsituted for the aromatic hydrogens. As a rule, halogen-, nitrogen-, or oxygen-substituted methyl groups are introduced and the substituents subsequently eliminated by catalytic hydrogenation or reduction

Scheme 10. Biosynthesis of tocotrienols and tocopherols

with zinc/hydrochloric acid. Hydroxymethylation with formaldehyde under acidic [370], alkaline [371], or neutral [372] conditions is the method of choice. Other processes are chloromethylation with formaldehyde and HCl [373] or $POCl_3$ [374]; formylation with zinc cyanide/ HCl, chloroform/alkali, or hexamethylenetetramine [375]; and Mannich aminomethylation [376].

4.11.2. Totally Synthetic Vitamin E: Industrial Synthesis

The industrial total synthesis of α-tocopherol (**1a**) is based on the condensation of 2,3,6-trimethylhydroquinone [*700-13-0*] (**7**) with phytol (**8**), phytyl halides, or preferentially isophytol (**9**).

Lewis and Brönsted acids [306], especially zinc chloride with a mineral acid [377], serve as catalysts for condensation. Boron trifluoride and $AlCl_3$ [378], Fe/HCl [379], trifluoracetic acid [380], and boric acid/carboxylic acid [381] are also good catalysts. A wide range of solvents can be used, e.g., ethyl acetate, acetic acid, (chlorinated) hydrocarbons or supercritical CO_2 [382].

When synthetic phytol (**8**) or isophytol (**9**) is used, the product consists of equal amounts of all eight α-tocopherol stereoisomers and is thus denominated (all-*rac*)-α-tocopherol.

The majority of synthetic α-tocopherol is treated with acetic anhydride to give the acetate, which is stable on storage. In addition, the succinate (monoester of succinic acid) [383] and the nicotinate are produced commercially. Purification of the crude product is possible at the free tocopherol or acetate stage by short-path distillation under high vacuum or extraction with supercritical CO_2 [384].

4.11.3. Trimethylhydroquinone

The starting material in the most important industrial syntheses of trimethylhydroquinone (**7**) is 2,3,6-trimethylphenol [*2416-94-6*] (**11**) [385], which is oxidized by oxygen or peroxides to give trimethylquinone (**13**) [*935-92-2*]. The catalysts mainly used are salcomin [386], copper chloride with diverse cocatalysts [387], or heteropoly acids [388]. Trimethylhydroquinone (**7**) is finally obtained by the catalytic hydrogenation of trimethylquinone (**13**) [389].

The intermediate 2,3,6-trimethylphenol (**11**) is produced from *m*-cresol (**12**) by catalytic alkylation with methanol [390].

Another important large-scale process for the synthesis of trimethylphenol (**11**) is the condensation of diethyl ketone with crotonaldehyde to yield trimethylcyclohexenone [*20030-30-2*] (**10**) [391] or diethyl ketone with methyl vinyl ketone to give trimethylcyclohexenone [*20030-29-9*] (**10′**) [392], followed by catalytic dehydrogenation of trimethylcyclohexenone to 2,3,6-trimethylphenol (**11**).

Still another synthesis of trimethylhydroquinone starts with mesitol (**14**) [393], which is

oxidized with oxygen [394] or hypochlorite or chlorine/water [395] to give trimethylquinol (**15**). Compound **15** is then rearranged by treatment with alkali [396] to yield trimethylhydroquinone (**7**). This pathway was long used by Rhône-Poulenc, but has now been replaced by oxidation of 2,3,6-trimethylphenol (**11**) with oxygen because oxidation with chlorine causes wastewater problems [397].

Trimethylhydroquinone (**7**) can also be made from the inexpensive compound isophoron (**16**). Oxidation to trimethylquinone (**13**) can be performed directly [398] or via the intermediate 2,3,5-trimethylphenol (**11′**), which gives **7** on hydrogenation [399]. Oxidation of **16** to oxoisophoron (**17**), followed by isomerization produces trimethylhydroquinone (**7**) directly [400]. These processes are, however, not used commercially.

4.11.4. Phytol and Isophytol

The key sequence in the formation of the vitamin E side chain is a series of C_2 and C_3 chain extensions, starting with a ketone.

The C_2 extension of the ketone proceeds via vinylation with vinyl Grignard or by ethynylation with subsequent partial hydrogenation. The allyl alcohol thus formed

is extended to give the γ,δ-unsaturated ketone (**18**) by means of acid catalyzed ketal formation/elimination/rearrangement with the C_3 building block 2-methoxypropene (Saucy–Marbet reaction [401]) or by transesterification/rearrangement with methyl acetoacetate (Carroll reaction [402]). The ketone (**18**) can be subjected to the same sequence again. The Saucy–Marbet reaction can also be applied to tertiary propargyl alcohols, forming the β-ketoallene (**18′**). In this case, partial hydrogenation after ethynylation is not required [403].

In this procedure, acetone is first converted to methyl heptenone [*110-93-0*] (**18**, R = Me), and then via linalool [*78-70-6*] (**19**) to geranylacetone [*689-67-8*] (**18**, R = prenyl), nerolidol [*1119-38-6*] (**20**) and farnesylacetone [*1117-52-8*] (**18**, R = geranyl), or their hydrogenation products. Hexahydrofarnesylacetone [*502-69-2*] is converted to isophytol (**9**), which can be isomerized to phytol (**8**) by acid-catalyzed rearrangement.

One of the four isophytol producers (Kuraray) makes methylheptenone (**18**, R = Me) from prenyl chloride and acetone [404]. In the late 1980s, Rhône-Poulenc changed its process, basing it on the inexpensive raw material myrcene (**21**) [*123-35-3*] [397], which yields geranylacetone (**18**, R = prenyl) in a rhodium-catalyzed reaction with methyl acetoacetate [405]. This compound is then further processed in the conventional way.

4.11.5. Stereoselective Syntheses of α-Tocopherol

In 1938, the first synthesis of (2*RS*,4′*R*,8′*R*)-α-tocopherol (**1a**) was conducted by KARRER et al. by the condensation of trimethylhydroquinone (**7**) and phytyl bromide (made from natural phytol) with zinc chloride [300].

This reaction was frequently modified [306]. Most of the α-tocopherol syntheses proceed via acid-catalyzed condensation of hydroquinone derivatives with phytol or isophytol derivatives. Tocopherols produced in these syntheses are always racemic at the C-2 center of the chromane ring.

The first synthesis of (2*R*,4′*R*,8′*R*)-α-tocopherol (**1a**) was conducted by MAYER et al [308] in conjunction with the elucidation of the absolute configuration. In this process, trimethylhydroquinone (**7**) was

converted to (2*R*,4′*R*,8′*R*)-tocopherol via chromanyl(ethinylcarboxylic acid) (**22**) – racemate separation was achieved via the quinine salt – and via the chromane carbaldehyde (**23**). The optically active side chain originated from natural phytol (**8**), which was converted to the corresponding Wittig reagent (Scheme 11).

Several modern total syntheses of (2*R*,4′*R*,8′*R*)-α-tocopherol were described in the late 1970s and early 1980s [406, 407]. These processes depended on the separation of racemic mixtures for the stereoselective formation of the chromane skeleton.

According to more recent results, the quaternary center at C-2 can be made by asymmetric synthesis, which uses either chiral auxiliaries in stoichiometric amounts [408, 409] (Scheme 12) or enantioselective catalytic processes [409, 410] (Scheme 13).

Enzymatic methods using tocopherol cyclases have also been successfully employed to generate the C-2 asymmetric center [356, 357, 411]. The γ-tocopherol initially obtained can be converted to the α-derivative by methylation (see Section 4.11.1).

1c

In the mid-1980s [412], an asymmetric catalytic hydrogenation process was developed for the synthesis of the enantiomerically pure side chain (Scheme 14).

This method has greatly improved the synthetic availability of the side chain with regard to both the number of reaction steps and the total yield. The enantiomeric excess achieved is 98.4 %. Nevertheless, compared with the availability of natural vitamin E, the effort involved in the commercial synthesis of (*R,R,R*)-tocopherol makes it uneconomical.

5. Vitamin K

5.1. Introduction; History

In 1929, while studying the metabolism of cholesterol in chickens fed a diet extracted with nonpolar solvents, Dam observed bleeding in various organs and tissues and a prolonged blood clotting time [413]. The symptoms could be prevented or cured by the feeding of plant or animal feedstuffs. Thus, Dam had discovered a new, essential, fat-soluble factor that controls the blood prothrombin level, which is important for blood clotting. In 1935, he suggested calling this factor vitamin K. At that time, the letter K was not only the next free letter for the designation of an existing or postulated vitamin, but K is also the first letter of the word for coagulation in German and the Scandinavian languages.

At the same time, Almquist found that an antihemorrhagic factor is also formed by bacteria in decaying feedstuffs (e.g., fish meal) [414]. In 1939/40, isolation, structural elucidation, and synthesis in various laboratories (Dam, Almquist, Karrer, Doisy, Fieser; see [413, 414]) showed surprisingly that two different forms of vitamin K occur in nature. They differ in the length and degree of saturation of the isoprenoid side chain linked to 2-methyl-1,4-naphthoquinone at C-3. Vitamin K_1 from plants has a mono-unsaturated C_{20} side chain, and bacterial vitamin K_2 has a polyunsaturated side chain of different length.

It was shown in 1974/75 that vitamin K functions as a cofactor for the γ-carboxylation of specific glutamic acid residues of the precursor protein of prothrombin, converting the protein to biologically active prothrombin [415].

1

The term vitamin K is now used as the generic name for 2-methyl-1,4-naphthoquinone and all derivatives that qualitatively exhibit the biological activity of phylloquinone (vitamin K_1) [416]. The following names have been recommended by IUPAC for the individual vitamins K [417]:

Phylloquinone, abbreviated K, previously vitamin K_1, for 2-methyl-3-phytyl-1,4-naphthoquinone. The U.S. Pharmacopoeia uses the name phytonadione [418]. The synonym phytomenadione is occasionally found in the

Scheme 11. Synthesis of (*R,R,R*)-α-tocopherol (**1a**)

Scheme 12. Asymmetric chromanol synthesis with chiral auxiliary

PTC = phase transfer catalyst

literature. Natural phylloquinone [*84-80-0*] (**1**) has the configuration 2′*E*,7′*R*,11′*R* [419].

2

Menaquinone-n (**2**), abbreviated MK-*n*, previously vitamin K_2, for 2-methyl-3-polyprenyl-1,4-naphthoquinone, *n* being the number of prenyl residues.

For instance, the compound originally isolated from rotting fish meal and named vitamin K_2 was later identified as menaquinone-7 (MK-7) [*2124-57-4*] (2-methyl-3-farnesylgeranylgeranyl-1,4-naphthoquinone) [419]. For MK-7, the older literature contains the designation vitamin $K_{2(35)}$ or vitamin K_2(35), which is no longer used. Menaquinones found in nature have side chains of 4 – 13 prenyl residues and usually exhibit the all-*trans* configuration.

Scheme 14. Synthesis of *R,R* side chain by catalytic hydrogenation

However, menaquinones with the *cis* configuration and partially saturated side chains also exist [420].

Menadione [*58-27-5*] (**3**), previously vitamin K_3, for 2-methyl-1,4-naphthoquinone. It does not occur in nature but can be converted to menaquinone-4 in the organism [421].

3

5.2. Physical Properties

All the vitamins K are lipophilic compounds which are readily soluble in ether, petroleum ether, benzene, hexane, and acetone, poorly soluble in methanol and ethanol, and insoluble in water. Due to the naphthoquinone chromophore, they have characteristic UV maxima (Table 14).

Table 14. UV maxima and extinctions ($E^{1\,\%}_{1\,cm}$) of phylloquinone and menaquinone-7 ($n = 7$) in petroleum ether [419]

Phylloquinone	Menaquinone-7
243 (395)	243 (278)
249 (420)	248 (295)
261 (390)	261 (266)
270 (392)	270 (267)
325 (68)	325 – 328 (48)

The infrared spectrum of vitamin K_1 and of all the K_2 vitamins shows intensive bands at 1660, 1618, 1300, and at 700 cm^{-1}, characteristic of the naphthoquinone ring [422].

In the 1960s, the ^1H NMR spectra were used for the determination of the configuration of the trisubstituted double bond in the side chain of vitamin K_1 [CH_3-C(3′): *trans*: 1.78 ppm, *cis*: 1.68 ppm] [423].

Vitamin K_1, phylloquinone 1 [422] is a viscous yellow oil at room temperature. It can be crystallized out at low temperatures in acetone or ethanol, *mp* −20 °C, *bp* 140 – 145 °C at 133 Pa, $[\alpha]^{20}_{D}$ −0.3° (dioxane), $C_{31}H_{46}O_2$, M_r 450.71, and ϱ 0.967 g/cm^3. It decomposes at normal pressure at 100 – 120 °C, but can be subjected to high vacuum distillation without appreciable decomposition. The redox potentials are 0.005 V (25 °C, 80 % ethanol, 0.02 molar in NaOAc and 0.02 molar in AcOH) and 0.363 V (20 °C, 95 % ethanol, 0.2 N in HCl and 0.02 molar in LiCl).

Vitamins K_2, menaquinone-n 2. A vitamin K_2 (menaquinone-7; **2**, $n = 7$) with *mp* 54 °C was first isolated in the pure form from rotting fish meal by Doisy in 1939 [424]. Most of the K_2 vitamins are light yellow, crystalline compounds. The melting points and the extinctions ($E^{1\,\%}_{1\,cm}$) at the UV maximum (248 nm) of menaquinone-*n* (**2**, $n = 1 – 10$) are presented in Table 15.

Table 15. Melting points and UV absorptions at 248 nm $E^{1\%}_{1cm}$ of menaquinones-n (n = 1 – 10) in petroleum ether [422]

n	$E^{1\%}_{1cm}$ (248 nm)	*mp*, °C
1	784	
2	617	53
3	496	35
4	440	35
5	363	39
6	320	50
7	295	54
8	268	56
9	246	56 – 57
10	224	62

The extinction $E^{1\%}_{1cm}$ of the K_2 vitamins decreases continuously with increasing chain length. In the structural elucidation, a comparison of these extinction values provided important information about the number of isoprene units in the side chain.

5.3. Chemical Properties [419]

General Aspects. The vitamins K are relatively heat resistant (≤100 °C) and stable in air. However, they are very sensitive to alkali and light. Therefore, they should always be protected from light.

Color Reactions. With sodium ethoxide, the vitamins K give a violet-blue color which, with time, changes to red and subsequently to brown (Dam – Karrer test) [425]. An intense blue color is also obtained with sodium diethyldithiocarbamate [426]. A stable orange color is produced by the reaction of the vitamins K with 5-imino-3-thioxo-1,2,4-dithiazolidine (Schilling – Dam test) [427].

Oxidation/Reduction. The structural elucidation of the vitamins K is based primarily on the oxidative degradation of the quinones and their hydroquinone diacetates. Chromic acid degradation of vitamin K_1 (**1**) yields a mixture of phthalic acid (**4**) and 2-methyl-1,4-naphthoquinone-3-acetic acid (**5**). Reductive acetylation of **1** gives dihydrovitamin K_1 diacetate [*604-87-5*] (**6**) which yields a mixture of diacetoxyaldehyde **7** and 6,10,14-trimethyl-2-pentadecanone (**8**) after ozonization (Scheme 15). On ozonolysis, dihydrovitamin K_2 diacetates (**9**) give the same diacetoxyaldehyde **7**, variable amounts of levulinic aldehyde (**10**) (depending on the chain length), and one equivalent of acetone (**11**) (Scheme 15).

Treatment of vitamin K_1 (**1**) with H_2O_2 in EtOH in the presence of Na_2CO_3 produces vitamin K_1 2,3-epoxide [*25486-55-9*] (**12**), which can be reduced to dihydrovitamin K_1 [*572-96-3*] (**13**) with sulfurous acid. Reduction of vitamin K_1 with sulfurous acid or with H_2/Lindlar catalyst also yields dihydrovitamin K_1 (**13**), which is, in turn, convertible to vitamin K_1 by reaction with oxidizing agents.

Scheme 15. Oxidation/reduction of vitamin K_1

Formation of Chromanol and Chromenol. Chromanols and chromenols regained importance after it was shown that the corresponding 6-phosphate derivatives of these compounds appear as intermediates in oxidative phosphorylation in cells.

Chemical conversion of vitamin K_1 (**1**) to chromanol (**14**) is achieved with tin(II) chloride. Cyclization to chromenol (**15**) is possible with pyridine or with sodium hydride.

5.4. Occurrence

Phylloquinone is widely distributed in higher plants and in green and blue algae. It is localized mainly in the chloroplasts [420]. Thus, green leafy vegetables contain relatively high amounts of phylloquinone (Table 16). The phylloquinone content is not considerably altered by cooking [429]. Comparatively little phylloquinone is present in fruit.

The vitamin K_1 content of some fruits (in μg/100 g fresh weight) is as follows [430]:

Avocados	20
Apples	5
Peaches	5
Bananas	1
Oranges	1
Pears	1
Pumpkins	1

Plant oils contain greatly varying amounts of vitamin K_1 (in µg/100 g) [431]:

Soybeans	193
Rapeseed	141
Olive	55.5
Sesame	15.5
Walnut	15
Safflower	9.1
Sunflower	9
Almond	6.7
Corn	2.9
Peanut	0.6

The phylloquinone concentration in plants can vary depending on genetic factors or on the site and degree of ripeness [432].

There is little information available on the vitamin K content of milk and meat products (Table 17). Apart from phylloquinone, the liver also contains long-chain menaquinones in concentrations several times higher than vitamin K_1. Relatively large amounts of menaquinones, especially of MK-9, are contained in cheese [434].

Table 17. Vitamin K content of milk and meat products [a] [430, 433]

Foods	Vitamin K content, µg/100 g
Cow's milk	0.5 – 1 [b]
Cheese	10 – 50 [c]
Butter	10 [c]
Skeletal meats	<1 – 5 [b]
Liver	20 – 100 [c]

[a] Determined by HPLC.
[b] Phylloquinone.
[c] Phylloquinone and menaquinones.

Menaquinones occur in certain, predominantly gram-positive bacteria. Other bacteria contain ubiquinones (**16**) with chain lengths of 6 – 10 prenyl residues instead of menaquinones. Some bacteria exhibit both quinones, usually with the same chain length. Among the menaquinones, MK-7 to MK-9 predominate. Those found in minor amounts are MK-4 to MK-6, and MK-10 to MK-13 [420]. In humans, some anaerobic intestinal bacteria produce mainly MK-6 to MK-13; MK-8 to MK-10 with two saturated isoprene units in the side chain (**17**) was also detected [435]. The menaquinones are localized in the cytoplasmic membranes of the bacteria. Their concentrations are in the range 0.6 – 1.7 mg/kg of bacterial dry weight [436].

16

17

$n = 5–7$

5.5. Biosynthesis

Both plants [437] and bacteria [438] use the same biosynthetic pathway for the formation of the naphthoquinone ring of vitamin K (Scheme 16). Shikimic acid (**18**) is made from the precursors erythrose 4-phosphate and phosphoenolpyruvic acid. After phosphorylation and reaction with phosphoenolpyruvic acid, shikimic acid is converted via chorismic acid (**19**) to isochorismic acid (**20**). In a complex reaction of the 2-succinylbenzoic acid synthase system [439], 2-oxoglutaric acid is decarboxylated in the presence of thiamine diphosphate (TPP), forming a succinylsemialdehyde-TPP carbanion (**21**). This substance then reacts with **20** yielding 2-succinyl-6-hydroxy-2,4-cyclohexadiene-1-carboxylic acid (**22**) after elimination of pyruvic acid. Aromatization of **22** produces 2-succinylbenzoic acid (**23**), which is converted to 1,4-dihydroxy-2-naphthoic acid (**25**) after activation via a coenzyme A ester **24** and a second aromatization step.

In the further biosynthesis of the vitamins K (Scheme 17), e.g., in the formation of bacterial menaquinones, **25** is condensed with polyprenyl diphosphate (**26**) to give 2-polyprenyl-1,4-naphthoquinol (**27**) on decarboxylation [436]. The methyl group of (*S*)-adenosyl-L-methionine is transferred to **27**, producing 2-methyl-3-polyprenyl-1,4-naphthoquinol (**28**), which yields menaquinone-*n* (**2**) on oxidation. The for-

Scheme 16. Biosynthesis of the naphthoquinone ring of vitamin K

mation of phylloquinone (**1**) proceeds analogously. In the same reaction sequence, phytyl diphosphate (**29**) is incorporated instead of the polyprenyl side chain. In the chloroplasts of plants, phytyl diphosphate is made from geranylgeranyl diphosphate by hydrogenation. However, phytylation and methylation of the corresponding vitamin K_1 precursors occur in separate membrane systems of the chloroplasts [440]. The synthesis of polyprenyl disphosphate starts with condensation of 1-isopentenyl diphosphate, which is formed from mevalonic acid, with the isomeric 3,3-dimethylallyl diphosphate to give geranyl diphosphate. Geranyl diphosphate is then extended by further coupling reactions with 1-isopentenyl diphosphate until the appropriate number of isoprene units in the side chain are obtained [420].

5.6. Chemical Synthesis

In 1939, the first syntheses of vitamin K_1 were published almost simultaneously by four groups [441] in connection with the structural elucidation. The starting materials were menadione (**3**) or menadiol (**30**) as the aromatic component and natural phytol (**31**) or one of its derivatives.

In the Fieser synthesis [443], which was the preferred method for a long time, an excess of menadiol [*481-85-6*] (**30**) was condensed with natural phytol [*150-86-7*] (**31**) in dioxane at 75 °C in the presence of oxalic acid as catalyst. The excess menadiol was subsequently extracted with dilute alkali and the alkylation product **13** was precipitated with petroleum ether.

Scheme 17. Biosynthesis of vitamins K

Oxidation of this waxy precipitate with silver oxide gave vitamin K_1 (**1**) in a total yield of ca. 30 % based on phytol (**31**).

A disadvantage of this synthesis is the Friedel – Crafts alkylation, which does not proceed regioselectively with regard to positions 2 and 3 of menadiol. In addition to the desired alkylation product **13**, almost equal amounts of the isomer **32** are produced. Furthermore, the acidic alkylation conditions cause partial isomerization of the trisubstituted double bond in the side chain. Under these conditions, phyllochromanol (**14**), a cyclization product of **13**, and phytadienes of type **33** are also formed.

With regard to commercial synthesis, a breakthrough was achieved in the 1950s when Isler et al. [445] at Hoffmann-LaRoche and Hirschmann et al. [446] at Merck found that monoacylated menadiols, e.g., the monoacetate **35a** or the monobenzoate **35b**, could be advantageously used in the alkylation step (Scheme 18). Thus, the undesired alkylation in position 2 of menadiol (**30**) is prevented. Moreover, it was found that boron trifluoride etherate is a much better catalyst than anhydrous oxalic acid and that natural phytol (**31**) can be replaced by isophytol [*505-32-8*] (**36**), which is easy to synthesize.

There are various processes available for the production of menadione (**3**). The most common is the oxidation of 2-methylnaphthalene with, e.g., CrO_3 or H_2O_2 in acetic acid or $Na_2Cr_2O_7$ in sulfuric acid [447].

Starting with menadione (**3**), the monobenzoate **35b** can be produced in three steps: catalytic reduction of menadione (**3**), e.g., in ethanol or methanol, followed by acylation with two equivalents of benzoyl chloride to give the dibenzoate **34b**, and partial saponification, e.g., with KOH or NaOH, to produce the desired monobenzoate **35b**. Menadiol monoacetate (**35a**) can be produced in an analogous manner and used for the synthesis of vitamin K_1 (**38**).

In the Isler – Lindlar method [445], excess menadiol monobenzoate (**35b**) is condensed with isophytol (**36**) in dibutyl ether at 85 °C in

the presence of boron trifluoride etherate as catalyst. Unreacted monobenzoate **35b** is precipitated with petroleum ether, filtered off, and recovered. After evaporation of the filtrate, the alkylation product **37b** is obtained as an *E*/*Z* mixture (*E*/*Z* 70 : 30). The *E* form can be enriched by recrystallization (e.g., from methanol/ethanol; USP requirement: $\leq$20 % of *Z* form in the final product vitamin K_1). **37b** can be obtained in the practically pure *E* form by repeated recrystallization.

Scheme 18. Synthesis of vitamin K_1

The *E*-enriched alkylation product **37b** (*E*/*Z* 9 : 1) is saponified with potassium hydroxide and oxidized to vitamin K_1 (**38**) with oxygen. In this method, *E*/*Z*-vitamin K_1 (**38**) is produced as a yellow oil in a yield of ca. 60 – 70 % based on isophytol (**36**).

For the synthesis of isophytol, see 4.11.4.

The fact that only *E*-vitamin K_1 exhibits K-activity in biological tests led to intensive work on this synthesis in the 1970s and 1980s, with the aim of synthesizing pure *E*-vitamin K_1.

Many multistage syntheses with organometallic reagents, e.g., Grignard reagents [448]; zinc reagents [449]; aryl [450] and vinyl cuprates [451]; trialkyltin compounds [452]; π-allylnickel [453]; phythaloylcobalt [454]; and chromium carbene complexes [455], have been published and patented. These and other synthetic possibilities are discussed in a review article [451].

In all these variants, a disadvantage is the use of stoichiometric amounts of organometallic reagents which must be recovered for economical and ecological reasons.

A potentially economic, short synthesis of vitamin K_1 and vitamins K_2 has been patented by F. Hoffmann-LaRoche [451,456] (Scheme 19).

Menadione (**3**) is first subjected to a Diels–Alder reaction with cyclopentadiene, producing the crystalline *endo*-Diels–Alder adduct [*97804-50-7*] **39** in 93 % yield. Subsequently, the proton α to the carbonyl group can be abstracted with a strong base (e.g., potassium *tert*-butoxide) and the resulting enolate alkylated with phytyl bromide (**40**) ($E/Z \geq 98:2$). The alkylation product **41** is obtained in a yield of $\geq$90 %. As a result of the basic alkylation conditions, the *trans* geometry of the double bond in phytyl bromide [*76524-59-9*] (**40**) ($\geq$98 % E) is completely retained during alkylation.

The alkylation product **41** [*97804-51-8*] is thermally unstable and undergoes a retro-Diels–Alder reaction. On heating in toluene (110 °C), it decomposes rapidly into vitamin K_1 (**38**) ($\geq$98 % E) and cyclopentadiene. The yield of vitamin K_1 is practically quantitative. The cyclopentadiene can be recovered by distillation and reused.

The vitamins K_2 (menaquinones) (**2**) and ubiquinones (**16**) can be synthesized according to the same scheme.

A patent application for a similar synthetic route to vitamins K and analogous compounds has been filed by Eisai Chemical Co. [457]. Instead of menadione (**3**), naphthoquinone (**42**) is used as starting material.

Analogously, the isoprenoid side chain [e.g., phytyl bromide (**40**)] and then the methyl groupare introduced via the cyclopentadiene adduct **43**. The intermediate **41** [451,456] described above is obtained via compound **44** and gives the desired quinone [e.g., vitamin K_1 (**38**)] after elimination of cyclopentadiene.

5.7. Analysis

Physicochemical Methods. As a result of its high selectivity and sensitivity, high performance liquid chromatography (HPLC) is the method of choice for the determination of phylloquinone and menaquinones in the blood, tissues, milk, and in foods. Various procedures for extraction and preliminary purification, internal standardization, HPLC conditions (with normal or reversed phase) and possibilities for UV, electrochemical, and fluorescence detection (both after electrochemical or chemical reduction and after photochemical decomposition) of the vitamins K have been described [458]. The detection limits for phylloquinone are in the range 25–500 pg, depending on the detection method employed [459]. Similar values that vary according to the length of the side chain apply to the menaquinones [460]. HPLC methods are also available for the determination of menadione and water-soluble derivatives (see Section 5.12) in feedstuffs, premixes, and in vitamin concentrates [458,461].

Alternative methods are thin layer chromatography (TLC) [462], high performance thin layer chromatography (HPTLC), and gas chromatography (GC) [458]. The spectrophotometric, fluorometric, and colorimetric methods previously used without chromatographic purification of the samples to be analyzed have the disadvantage of low sensitivity and specificity. They are unable to distinguish between phylloquinone and menaquinones [436,462]. The detection limits are ca. 25 µg/mL for phylloquinone and menadione.

Biological methods measure the biological activity of a specific vitamin K compound or detect vitamin K activity in a sample under analysis. It is not possible to differentiate between definite forms of vitamin K in the sample. The biological methods are based on the measurement of the prolonged blood clotting time (prothrombin time) in vitamin K deficient animals (chicks, rats) and its normalization after the administration of the sample exhibiting antihemorrhagic activity [463]. The bioavailability and biopotency of formulated vitamin K compounds are tested mainly in the prophylactic test, i.e., after intermixing with vitamin K deficient feed and feeding for a period of 24 d [464]. On the other hand, the vitamin K activity of pure substances is determined after a single dose in the curative test [465]. The biological determination of vitamin K can also be conducted in animals that have prolonged blood clotting times caused by the feeding of anticoagulants (see Section 5.9.2). Strictly speaking, however, this test does not measure the reversal of vitamin K deficiency, but the competition between the vitamin K compound to be tested and the antagonist used.

Scheme 19. Synthesis of vitamins K (Hoffmann-LaRoche)

5.8. Metabolism

Alkylation of Menadione. Menadione (vitamin K_3) itself has no antihemorrhagic activity. However, it can be prenylated to active menaquinone-4 in the liver and in other animal tissues [421].

Intestinal bacteria can form menadione by eliminating the phytyl side chain of phylloquinone. After absorption, menadione is converted to MK-4 in the animal organism [433]. It appears possible that dealkylation of phylloquinone and, consequently, conversion of vitamin K_1 to MK-4 can occur in animal tissues as well [466, 467].

Absorption. Phylloquinone and menaquinones present in food are absorbed in the proximal small intestine. Sufficient amounts of bile and pancreatic juice enzymes are required in the intestinal lumen so that the vitamins K can be emulsified in the mixed micelles consisting of bile salts, fatty acids, and monoglycerides, before they are absorbed by the intestinal mucosa cells [468]. A saturable, energy-dependent mechanism that cannot be influenced by the menaquinones seems to be responsible for the absorption of phylloquinone [433]. In the case of the menaquinones produced by intestinal bacteria, absorption occurs in the large intestine by passive diffusion [434]. In the intestinal cells, the absorbed vitamins K are incorporated into chylomicrons and transported to the liver via the lymph. The degree of absorption for vitamin K in the small intestine is 40 – 70 % [469].

The absorption of menadione occurs in the distal small and large intestine by a passive,

energy-independent process. It enters the blood stream directly from the intestine [470].

Distribution. A part of the vitamin K transported to the liver is incorporated into VLDL (very low density lipoproteins), released into the blood stream, and transferred via LDL (low density lipoproteins) to other organs [436] (e.g., lungs, kidneys, adrenals, bone marrow, lymph nodes [421], testicles, and skin [471]). The part remaining in the liver, which is the main site of activity of vitamins K, is mainly taken up by the mitochondria and the microsomes [433].

The distribution of the various forms of vitamin K in the organism varies greatly. Phylloquinone is only moderately retained in the liver. It has a half life of ca. 17 h in rat liver [433]. In human liver, the average concentration of phylloquinone is 5.5 ng/g (range: 1.1 – 21.3 ng/g for 32 individuals tested: $N = 32$) [472]. In contrast to phylloquinone, the more lipophilic menaquinones have a longer retention time or slower turnover in the liver [434], which can lead to a certain accumulation (Table 18). The menaquinones account on an average for 92 mol % of the total vitamin K content of the adult human liver (individual variations of 75 –97 %) [472]. With the exception of horse liver, in which only phylloquinone could be detected, considerable amounts of menaquinones are also present in the liver of other animal species. Bovine liver contains mainly MK-10 to MK-12, while in dog and pig liver MK-8 to MK-10 predominate [436]. Chicken liver contains much more MK-4 than phylloquinone [466]. In rats, relatively high levels of MK-4 are found in the pancreas and salivary gland [467].

Compared to liver, the ratio of phylloquinone to menaquinones in human blood plasma is substantially shifted (Table 18). The menaquinones exceed the amount of phylloquinone only by a factor of 1.2 – 2.3, and very long chain menaquinones (MK-9 to MK-13) are no longer found. This is another indication of a slower hepatic turnover of the highly lipophilic menaquinones and their greater affinity for intracellular membranes. The average phylloquinone concentration in the plasma is 0.485 ± 0.314 ng/mL ($N = 332$) [475].

Breast milk can contain low concentrations of MK-5 to MK-7, but the main form of vitamin K present is phylloquinone [459,476]. Its concentration fluctuates between 1.1 and 6.5 ng/mL (average 2.1 ng/mL). Cow's milk has a much higher phylloquinone content: 10 – 20 ng/mL [436].

In the organism, menadione is distributed over many tissues, but very rapidly eliminated. Only a small part of menadione is converted to menaquinone-4 [421].

Degradation and Excretion. In studies on the catabolism of phylloquinone (**38**) in humans and laboratory animals, the following metabolites were identified [477]: 2-methyl-3-(7′-carboxy-3′,7′-dimethyl-2′-heptenyl)-1,4-naphtho- quinone (**46**), 2-methyl-3-(5′-carboxy-3′-methyl-2′-pentenyl)-1,4-naphthoquinone (**47**), and 2-methyl-3-(3′-carboxy-3′-methyl-propyl)-1,4-naph-thoquinone (**48**). They are produced from **38** by ω-oxidation to the corresponding carboxylic acid **45**, followed by

Table 18. Concentration of vitamin K in human liver and blood plasma (ng/g liver or ng/mL plasma)

Vitamin K form	Liver, $N = 7$ [473]	Plasma $N = 22$ [473]	Plasma $N = 11$ [474]
K_1	12.6 ± 1.9	0.59 ± 0.06	0.51 ± 0.37
MK-4	0.4 ± 0.2	0.05 ± 0.01	
MK-6		0.05 ± 0.01	
MK-7	21.8 ± 7.8	0.57 ± 0.08	0.29 ± 0.18
MK-8	6.3 ± 1.2	0.08 ± 0.05	0.54 ± 0.32
MK-9	1.5 ± 0.5		
MK-10	62.6 ± 8.0		
MK-11	89.0 ± 13.4		
MK-12	13.3 ± 2.4		
MK-13	5.0 ± 1.4		

repeated β-oxidation of the side chain. After reduction to 1,4-naphthohydroquinone and conjunction with glucuronic acid, the metabolites are excreted in the urine as mono- or diglucuronides. A part of the less polar

metabolites is also excreted in the conjugated form via the bile and feces [478]. Menaquinones (like ubiquinones (**16**) and tocopherols) are degraded in the same manner.

Menadione is also excreted in the urine in the conjugated form as the phosphate, sulfate, or glucuronide of menadiol (**30**).

5.9. Importance for the Organism

5.9.1. Function

Vitamin K plays a vital role as a cofactor in the γ-carboxylation of specific glutamic acid residues near the amino terminal end of seven protein precursors of the blood clotting system (see also → Blood, Chap. 2.2.2.) [479]. This post-translational modification of inactive preproteins produces active coagulation proteins (Table 19) with 10 – 13 γ-carboxyglutamic acid residues per molecule. In the presence of calcium ions, these residues allow the proteins to bind to phospholipid membrane surfaces [436]. The classical vitamin K dependent factors II, VII, IX, X, and protein C can thereby perform their specific functions (Table 19) within the complex blood clotting system. The overall function of this system is maintenance of normal hemostasis, i.e., the absence of hemorrhagic or thrombic events. In principle the reactions of the blood clotting system proceed in such a manner that in conjunction with additional components of an activation complex, an activated clotting factor converts an inactive clotting factor to an active proteolytic enzyme. This enzyme, in turn, acts as a proteinase in the next step of the blood clotting cascade. The last activation step involves the conversion of prothrombin (factor II) to thrombin, which finally causes the formation of fibrin from its precursor fibrinogen, producing a stable fibrin clot. The coagulation proteins are synthesized in the liver and then released into the blood. In vitamin K deficiency, the blood clotting proteins are produced, but they remain inactive because of insufficient or lacking γ-carboxylation of the glutamic acid residues [469].

The form of vitamin K that is "active" as a cofactor for the γ-glutamyl carboxylase located in the microsomes (E1 in Scheme 20) is 1,4-dihydrovitamin K (**50**). Simultaneous with the carboxylation of a protein-bound glutamyl residue (**51**) to a γ-carboxyglutamyl residue (**52**), 1,4-dihydrovitamin K is oxidized to the 2,3-epoxide of vitamin K (**53**) [481]. It is assumed that carboxylation and epoxidation are catalyzed by the same enzyme [434]. The epoxide **53** is then reduced to vitamin K (**49**) by a dithiol-dependent vitamin K epoxide reductase (E2). Another dithiol-dependent vitamin K reductase (E3) reforms vitamin K hydroquinone (**50**). It is possible that the reduction (E3) of **49** to **50** is also carried out by vitamin K epoxide reductase (E2). However, vitamin K can also be reduced to the quinol **50** by a NAD(P)H-dependent vitamin K reductase (E4). The activity of the dithiol-dependent reductases (E2 and E3) is inhibited by anticoagulants (A) (see Section 5.9.2).

Table 19. Vitamin K dependent proteins of the blood clotting system [480]

Protein	Function	Molecular mass	Concentration in human blood, ng/mL
Factor VII (proconvertin)	activation of factor X to X a	48 000	0.6
Factor IX (PTC ∗)	activation of factor X to X a	57 000	5
Factor X (Stuart – Prower Factor)	as factor X a: conversion of factor II to thrombin	55 000	10
Factor II (prothrombin)	precursor of thrombin	72 000	100
Protein C	inhibition of coagulation	62 000	4 – 5
Protein S	cofactor of protein C	80 000	25

Scheme 20. Reactions of the vitamin K cycle
R = phytyl (phylloquinone) or geranylgeranyl (MK-4); 1E1 = γ-glutamyl carboxylase; E2 = vitamin K epoxide reductase; E3 = dithiol-dependent vitamin K reductase; E4 = NAD(P)H-dependent vitamin K reductase; D-$(SH)_2$ = reduced dithiol; D-S_2 = oxidized dithiol (functional dithiols: dithiothreitol and thioredoxin); NAD(P)H = reduced nicotinamide adenine dinucleotide (phosphate); $NAD(P)^+$ = oxidized nicotinamide adenine dinucleotide (phosphate); A = inhibition by anticoagulants

This vitamin K (or vitamin K epoxide) cycle acts very effectively. It is assumed that one molecule of vitamin K is recycled several thousand times before it is converted to inactive metabolites [482]. Approximately 10 % of the phylloquinone in the liver is present as phylloquinone-2,3-epoxide [483]. Menaquinones, especially MK-3 and MK-4, are also active in the vitamin K cycle. However, their activity decreases with increasing length of the side chain (see Section 5.9.3). Menadione cannot replace the vitamins K.

After the elucidation of the cofactor role of vitamin K in the formation of γ-carboxyglutamic acid (Gla) in the vitamin K dependent blood clotting factors in the liver, it was observed that the vitamin K cycle is active in other tissues as well (e.g., bone, cartilage, kidney, spleen, and lung). In fact, various organs form Gla-containing proteins which are not involved in blood clotting [434, 484]. Little is known about the function of these proteins. Until now, the bone Gla-protein (osteocalcin) and the matrix Gla-protein have been relatively well studied. Osteocalcin is produced by the osteoblasts of bone tissue, approximately 30 % of this protein being released into the blood [482]. Osteocalcin, which is subject to regulation by 1,25-dihydroxyvitamin D_3, is quantitatively the most common noncollagenic protein component of the bone matrix and accounts for ca. 2 % of the total proteins of the bone. In addition, it is quantitatively the most common vitamin K dependent protein in the body [436]. It is assumed that the Gla-containing part of osteocalcin plays an important role in mineralization or demineralization of the bone. The matrix Gla-protein, which is formed in a series of organs (especially heart,lung, kidney, and cartilage tissue), is enriched above all in the bone and cartilage. It probably has a mediator function in cell growth and differentiation [485].

These examples show that vitamin K not only plays a specific role in blood clotting, but this vitamin apparently has a wider biological significance (see Section 5.10.1) which is connected with the strong calcium-binding properties of the negatively charged Gla residues in vitamin K dependent proteins.

In plants, phylloquinone acts as an electron carrier in the chloroplasts. In the plasma membrane of bacteria, menaquinones are involved as redox substances in electron transport and oxidative phosphorylation [486].

5.9.2. Antagonists and Anticoagulants

Around 1930, a hemorrhagic disease was observed in cattle in Canada and the United States and was put down to spoilt sweet clover hay fodder. In 1941, the substance responsible for this disease was identified by isolation and structural elucidation as 3,3′-methylene-bis-(4-hydroxycoumarin), usually called dicumarol (**54**) [433]. This led to the synthesis of other derivatives of 4-hydroxycoumarin which can be used in the treatment of thromboembolic diseases and for the prevention of thrombus formation in vessels. Active oral anticoagulants are, e.g., phenprocumarol [3-(1′-phenylpropyl)-4-hydroxycoumarin] (**55**), warfarin [3-(α-acetonylbenzyl)-4-hydroxycoumarin] (**56**), acenocumarol [3-(α-acetonyl-4-nitrobenzyl)-4-hydroxycoumarin] (**57**), and ethyl-biscoumacetate [3,3′-carboxymethylene-bis-(4-hydroxycoumarin) ethyl ester] (**58**) [487].

The action of all oral anticoagulants is based on the inhibition (A in Scheme 20) of vitamin K epoxide reductase (E2) and of dithiol-dependent vitamin K reductase (E3) in the vitamin K cycle. This leads to an increase in the concentration of vitamin K 2,3-epoxide (**53**) in the liver, a decrease in the activity of the blood clotting proteins due to lacking γ-carboxyglutamic acid formation and, consequently, to an increase in the blood clotting time [434]. Since oral anticoagulants inhibit the dithiol-dependent vitamin K reductase (E3) but not the NAD(P)H-dependent reductase (E4), inhibition of the vitamin K cycle can be avoided by large doses of phylloquinone. Under these conditions, however, the 1,4-dihydrophylloquinone (**50**) formed can only act to a limited extent because the recycling of vitamin K_1 epoxide is inhibited or blocked. The result is a relatively high vitamin K epoxide level in the blood. Oral anticoagulants interfere not

only with the vitamin K cycle in the liver, but also in other organs. A decrease of at least 50 % in the blood level of osteocalcin and a reduction of the γ-carboxyglutamic acid content of osteocalcin by 50 % have been observed under therapy conditions [482].

More effective, extremely lipophilic derivatives of 4-hydroxycoumarin have now been synthesized for use as rodenticides (→ Rodenticides, Chap. 5.3.). Examples are difenacoum (**59a**) and brodifacoum (**59b**). These substances have a very long biological half life of 100 – 200 d. They are potentially harmful to humans [434].

59a: R = H
59b: R = Br

A competitive inhibitor of vitamin K is 2-chloro-3-phytyl-1,4-naphthoquinone (**60**), also known as chloro-K. It inhibits the γ-glutamyl carboxylase reaction (E1 in Scheme 20) by preventing epoxidation of vitamin K. 2,3,5,6-Tetrachloro-4-pyridinol (**61**) which is structurally related neither to vitamin K nor to 4-hydroxycoumarin, inhibits the carboxylase apparently as a direct antagonist of the vitamin [433, 484].

60

61

5.9.3. Relative Activity

Studies of the biological activity of vitamin K clearly show that two structural elements are required: a 2-methyl-3-substituted 1,4-naphthoquinone ring which can be reduced to hydroquinone, and a side chain at the C-3 atom which guarantees binding to or interaction with microsomal membranes.

Totally synthetic phylloquinone (**38**) consists of an equimolar mixture of four stereoisomers ((**62a**), (**62b**),(**62c**), (**62d**)). In curative prothrombin-time chick assays (see Section 5.7), no substantial differences were found in their antihemorrhagic activity [488] (Table 20).

Table 20. Antihemorrhagic activity of the stereoisomers of phylloquinone and of (E, all-rac)-phylloquinone [488]

Compound	Configuration	Activity, %	Confidencelimits
62a	2′*E*,7′*R*,11′*R* (standard)	100	88 – 116
62b	2′*E*,7′*R*,11′*S*	93	75 – 115
62c	2′*E*,7′*S*,11′*S*	119	110 – 128
62d	2′*E*,7′*S*,11′*R*	99	88 – 111
38	2′*E*,7′*RS*,11′*RS* (*E*, all-*rac*)	111	100 – 122

62

Although **62c** and (*E*, all-*rac*)-phylloquinone (**38**) have a slightly higher biological activity than natural phylloquinone (**62a = 1**), all four stereoisomers and **38** are to be considered identical with regard to biological activity within the statistical confidence limits [488]. Totally synthetic commercial phylloquinone always contains a low proportion (up to 10 %) of (*Z*, all-*rac*)-phylloquinone (**65**). However, the antihemorrhagic activity of **65** is only 0.3 – 1 % (Table 21) and thus, negligible [489].

Phylloquinone-2,3-epoxide (**12**), the main component of the vitamin K cycle (see Section 5.9.1), is 1.66 times as active as phylloquinone (Table 21). Changes in the side chain, e.g., 6′-hydroxylation (**63**) or hydrogenation of the double bond of the side chain (**64**), result in a great decrease in the biological activity. If, in addition, the naphthoquinone ring

Table 21. Antihemorrhagic activity of structural analogs of phylloquinone (K_1) [465,489]

Compound	Structure	Activity, %	Confidence limits
38	(2′*E*,7′*RS*,11′*RS*)-K_1 (standard)	100	87.8 – 116.7
12	(2′*E*,7′*RS*,11′*RS*)-K_1 2,3-epoxide	166	137.3 – 200.2
63	(2′*E*,7′*RS*,11′*RS*)-6′-hydroxy-K_1	20.5	16.1 – 26.0
64	(3′*RS*,7′*RS*,11′*RS*)-2′,3′-dihydro-K_1	6.7	5.1 – 8.8
65	(2′*Z*,7′*RS*,11′*RS*)-K_1	<1	

is also partially hydrogenated to 2′,3′,5,6,7,8-hexahydrophylloquinone (**66**), the biological activity is totally lost [465]. Substitution of the phytyl side chain of phylloquinone by an unbranched alkyl side chain (e.g., 2-methyl-3-octadecyl-1,4-naphthoquinone) also causes a major loss of biological activity [420,421].

The length of the isoprenoid side chain is also of importance. In the prothrombin-time assay in vitamin K deficient chicks (Table 22), comparisons of the antihemorrhagic activity of isoprenologs of phylloquinone and menaquinones (on a molar basis) showed that a C_{20} side chain (four isoprene units) is optimal for the phylloquinone series. In the case of the menaquinones, MK-5 is 20 % more active than phylloquinone, while MK-4 and MK-6 have the same activity as vitamin K_1. The biological activity of the menaquinones decreases with increasing length of the side chain [487]. Kinetic studies on the cofactor activity of the menaquinones, measured as the reaction rate of partially purified γ-glutamic acid carboxylase at saturating vitamin concentrations, confirm that the activity depends on the length of the side chain (Table 23). In this study MK-3 had optimal activity, MK-2 and MK-4 were almost as active as phylloquinone, while the activity steadily decreases from MK-5 to MK-10 [490].

Table 22. Antihemorrhagic activity of isoprenologs of phylloquinone and menaquinones [487]

Phylloquinone series		Menaquinone series

MK-10	13.0	51.2

5.10. Deficiency Symptoms

5.10.1. Causes

Vitamin K deficiency leads to the secretion of incompletely carboxylated, biologically less active or inactive forms of the blood clotting factors II, VII, IX, and X (see Section 5.9.1) and, consequently, to subcutaneous or organ bleeding. Vitamin K deficiency can result from inadequate dietary supply or from diseases which interfere with the absorption of the vitamin in the intestine. Examples are pancreatic insufficiency and biliary obstruction (lack of pancreatic enzymes and bile salts for the solubilization of vitamin K, see Section 5.8), intestinal diseases (malabsorption of vitamins), or parenteral nutrition (if not supplemented with vitamin K) [468]. In liver diseases, the protein synthesis of the blood clotting factors can be reduced so that in spite of an adequate supply of vitamin K, there can be a quantitative lack of circulating blood clotting factors [480]. As in true vitamin K deficiency, therapeutic treatment of patients with anticoagulants produces a qualitative lack of the blood clotting factors II, VII, IX, and X (see Section 5.9.2). The effect of anticoagulants can be reversed by high doses of vitamin K. Whether a decrease in the synthesis of menaquinones in intestinal bacteria due to antibiotics or sulfonamides can cause vitamin K deficiency is still unknown (see Section 5.11).

In healthy adults, the risk of vitamin K deficiency is very low under normal nutritional conditions. Newborn infants, however, have a relatively high risk of developing hemorrhagic disease of the newborn (HDN). If newborn infants are not prophylactically treated with vitamin K, 2.5 – 5 per 1000 infants suffer from HDN [491]. This disease is manifested in bleeding (e.g., in the gastrointestinal tract), which can appear on the first day (early HDN) or in the first week after birth (classical HDN). In late HDN (2nd to 10th week), dangerous and often fatal intracranial bleeding occurs [434]. The cause of HDN is a lack of blood clotting factors in the blood of the newborn as a result of an inadequate supply of vitamin K. This is due to the low permeability of the placenta for vitamin K, limiting the transport of the vitamin from the blood of the mother to the fetus. The lack of an intestinal flora, i.e., absence of menaquinone production in the newborn during the first days of life, can also play a part [471]. Another serious factor is that breast milk is a relatively poor source of vitamin K. Consequently, newborns can cover only about 20 % of their daily vitamin K requirement [469]. The requirement of newborn infants is relatively high because vitamin K is not only needed in the liver for the formation of active blood clotting factors, but rapidly growing bones also require a considerable amount of vitamin K for the synthesis of active osteocalcin [471]. In many countries, newborns are prophylactically given 1 mg of phylloquinone at birth to prevent HDN [492].

It is possible that postmenopausal women also bear a risk of becoming deficient in vitamin K. In patients suffering from osteoporosis, a decrease in the plasma concentration of phylloquinone of up to 30 % of the normal value [493] and insufficient γ-glutamyl carboxylation of the circulating osteocalcin at normal prothrombin values have been observed [482]. Administration of vitamin K to these patients increased not only the plasma level of osteocalcin and the content of γ-carboxyglutamic acid, but also reduced by 50 % the previously increased excretion of calcium in the urine [471]. However, the physiological significance of these results and the association between dietary or subclinical vitamin K deficiency and the pathogenesis of osteoporosis must be further investigated [494].

With regard to animal nutrition, in particular pigs deficient in vitamin K suffer from subcutaneous hemorrhage [495]. Shortly after weaning, young piglets can develop severe internal and external bleeding, a condition called porcine hemorrhagic syndrome. The causes are an insufficient vitamin K content of the feed and sulfonamide/antibiotic medication [496].

5.10.2. Evaluation of Vitamin K Status

In principle, two methods are available for the evaluation of vitamin K status in humans and animals: the quantitative determination of vitamin K in the blood or organs by HPLC (see Section 5.7) or the mostly indirect detection of prothrombin or other vitamin K dependent proteins in the plasma.

The general blood clotting tests for the determination of the prothrombin time [480] have a low sensitivity. They are either more sensi-

tive to the concentration of factor VII than to prothrombin or they do not respond to a mild vitamin K deficiency [433, 482]. For this reason, it is better to determine under-γ-carboxylated prothrombin, i.e., prothrombin containing little or no γ-carboxyglutamic acid residues (often called PIVKA, prothrombin induced by vitamin K absence or antagonists). The prothrombin time is measured in one sample after activation of prothrombin with thromboplastin (only completely carboxylated prothrombin is activated) and in another sample, after activation of prothrombin with a certain snake venom (which activates both normal and under-γ-carboxylated prothrombin, i.e., total prothrombin). The ratio of the two test results is normally ca. 1, but <1 under conditions of vitamin K deficiency [497, 498]. PIVKA can also be directly determined cross-immuno-electrophoretically or by using monoclonal or monospecific antibodies [498]. There are, however, two limitations on the detection of PIVKA: abnormal prothrombin is a very heterogeneous molecule and, therefore, it is unknown to what extent various forms of PIVKA react in the different methods. In addition, abnormal prothrombin is also found in the plasma of patients suffering from hepatic cancer or other liver diseases [499]. Parallel determinations of the vitamin K concentration in the blood and of intact and/or abnormal prothrombin may be necessary to evaluate the vitamin K status more accurately.

In vitamin K deficiency, under-γ-carboxylated osteocalcin has been detected in the plasma by means of a radio-immunological method [498]. However, further studies are necessary to clarify whether this parameter is suitable for the evaluation of vitamin K status or can even be used as an early indicator of vitamin K deficiency. This also applies to the excretion of γ-carboxyglutamic acid (Gla), which results from the degradation of vitamin K dependent proteins and could serve as an indicator for the assessment of vitamin K deficiency. In combination with the determination of the plasma vitamin K_1 level, the measurement of Gla in the urine appears to be useful [475].

5.11. Requirement

The daily vitamin K requirement of a healthy human is generally estimated at 1 – 2 µg/kg of body weight [500]. In 1989, the U.S. National Research Council first published recommended dietary allowances for vitamin K of 1 µg per kg of body weight per day (Table 24) [469]. For babies, the recommended daily dose is 5 µg of vitamin K for the first six months and 10 µg for the second six months on condition that newborn infants are prophylactically given at least 1 mg of vitamin K at birth to prevent bleeding (see Section 5.10.1). For pregnant or nursing women, an increase in the vitamin K requirement is not considered necessary [469].

Table 24. Daily vitamin K intake recommended (1989) by the U.S. National Research Council for man [469]

Category	Age, a	Weight, kg	Vitamin K, µg
Small children	0 – 0.5	6	5
	0.5 – 1	9	10
Children	1 – 3	13	15
	4 – 6	20	20
	7 – 10	28	30
Young males and men	11 – 14	45	45
	15 – 18	66	65
	19 – 24	72	70
	25 – 50	79	80
	>51	77	80
Young females and women	11 – 14	46	45
	15 – 18	55	55
	19 – 24	58	60
	25 – 50	63	65
	>51	65	65

The amount of vitamin K in the diet consumed daily by a healthy American adult is estimated to be 300 – 500 µg. This estimate is probably too high [469]. In general, however, it can be assumed that the quantity of vitamin K in the daily diet is fully sufficient to cover the requirement under normal nutritional conditions. However, it is doubtful whether the earlier assumption that the menaquinones formed by intestinal bacteria contribute partially or completely to meeting the human vitamin K requirement is correct. Studies on volunteers showed that a restriction of the phylloquinone supply to 2 – 5 µg/d for a period of two weeks caused a significant decrease in the blood clotting factor VII and an increase in the concentration of insufficiently γ-carboxylated (abnormal) prothrombin in the plasma (see Section 5.10.2), although

the relatively insensitive measurements of the prothrombin time remained in the normal range [501]. In a second study on students, a reduction by 50 % of the daily supply of vitamin K_1 (from 82 to 32 – 40 µg/d) for a period of three weeks resulted in a significant decrease in the serum level of phylloquinone, formation of abnormal prothrombin, and a significant reduction in the excretion of γ-carboxyglutamic acid in the urine [497]. These results show that dietary phylloquinone is very important for humans and that long-chain bacterial menaquinones are not able to prevent the appearance of vitamin K deficiency symptoms. The reasons for this include the highly lipophilic properties, lower bioavailability [499], slower turnover, and lower biological activity of long-chain menaquinones (see Section 5.9.3).

The vitamin K requirement of some animal species is given in Table 25. The high requirement of poultry is remarkable and was attributed to insufficient absorption of the vitamin from their short digestive tract. However, more recent results have shown that the activity of vitamin K epoxide reductase (see also Section 5.9.1) in chicken liver is ten times lower than in the rat. This results in high concentrations of vitamin K 2,3-epoxide in the liver and serum of the chicken [466]. In pigs, an increase in the calcium content of the feed results in a higher vitamin K requirement [502], indicating that there is a relationship between calcium homeostasis and vitamin K supply.

Table 25. Vitamin K requirement of various animal species [433]

Species	Requirement, µg/kg body weight per day	Amount in feed, µg/kg
Dog	1.25	60
Pig	5	50 ∗
Rat (male)	11 – 16	100 – 150
Chicken	80 – 120	530
Turkey	180 – 270	1200

∗ Other authors recommend a concentration of 500 –2000 µg vitamin K_3/kg feed [495, 496].

5.12. Application

Phylloquinone is the preferred form of vitamin K for clinical application. The main indications are:

1) Prophylactic treatment of newborn infants to prevent hemorrhagic disease of the newborn
2) Treatment of vitamin K deficiency caused by disturbances of absorption in various diseases (e.g., pancreatic insufficiency, biliary obstruction, lipid malabsorption), insufficient alimentary supply, or parenteral nutrition
3) Countertreatment of anticoagulant therapy
4) Prophylactic administration before operations in which bleeding can become a problem (e.g., gallbladder operations)

In Japan, menaquinone-4 (menatetrenone) is used for the prevention of hemorrhagic disease of the newborn [490].

67

68

69

70

In animal nutrition (pigs and especially poultry), water-soluble forms of menadione are mainly used to cover the vitamin K requirement because phylloquinone is too expensive for this application. Menadione itself is less suitable for this purpose because it is instable in feed and its absorption in the intestine depends on the presence of lipids in the feed [433]. The most common water-soluble forms of menadione (**3**) are menadione sodium bisulfite (MSB) (**67**); menadione sodium bisulfite complex (MSBC) (**68**); menadione dimethylpyrimidinol bisulfite, known as menadione pyrimidinol bisulfite (MPB) (**69**) [495]; and menadione nicotinamide bisulfite (MNB) (**70**) [503]. MSBC (**68**) is still more stable than MSB (**67**) and, therefore, is widely used in poul-

try feeding. In chickens, all these compounds exhibit approximately the same biological activity on a molar basis as phylloquinone [504]. Menadione is readily converted to menaquinone-4 in the body of the chicken.

5.13. Tolerance

Toxic effects of phylloquinone and menaquinones are so far unknown. Very rare cases of cardiopulmonary reactions observed on intravenous administration of phylloquinone were due to the use of auxiliary agents for the emulsification of the vitamin [470]. Intramuscular injections of water-miscible formulations of phylloquinone are unproblematic [495].

71

Today, parenteral administration of menadione or of water-soluble forms such as menadiol sodium diphosphate (**71**) is no longer employed. Menadione can react with free sulfhydryl groups in various tissues, causing hemolytic anemias, hyperbilirubinemia, and kernicterus [433]. This side effect of menadione is not connected with its conversion to menaquinone-4 in the organism, but is due to its chemical properties as a quinone. For this reason, phylloquinone (or menaquinone-4 in Japan) is used exclusively today in the medical treatment of hemorrhagic diseases and in the prophylactic treatment of newborn infants.

In animal nutrition, menadione and water-soluble forms are well tolerated when administered orally within the dosage range. While the LD_{50} for a single parenteral application of menadione is 75 – 200 mg/kg of body weight in the chicken, mouse, or rat, the LD_{50} for a single oral dose is 600 – 800 mg/kg of body weight. This means that side effects would only be expected if the amount of menadione ingested daily with the feed exceeds the daily requirement by a factor of 1000 [504].

5.14. Trade Names and Economic Aspects

Phylloquinone is available for parenteral application in the form of colloidal suspensions, emulsions, and aqueous suspensions and for oral application in the form of tablets and mixed micelle solutions. In Japan, preparations containing menaquinone-4 are also available. The products sold are, e.g., Konakion, Konakion MM, Mephyton, Aquamephyton, and Kay-two (menatetrenone).

World production of phylloquinone is estimated at 3000 – 3500 kg/a. The main producers are Roche, Merck, Eisai, and Nisshin Chemical.

Water-soluble forms of menadione are mainly produced in feed-grade quality as feed additive for poultry feed and other animal feed (e.g., for pigs). The worldwide demand for menadione derivatives is ca. 500 t/a. The main producers are Vanetta and Heterochemical.

6. Vitamin B_1 (Thiamin)

6.1. Structure and Nomenclature

Vitamin B_1 (**1a**) has the IUPAC – IUB name thiamin [*59-43-8*], although the term thiamine is used in many official and commercial documents.

The basic skeleton of thiamin contains a thiazole ring and a pyrimidine ring. The exact chemical nomenclature is 3-[(4-amino-2-methylpyrimidin-5-yl)methyl]-5-(2-hydroxyethyl)-4-methylthiazolium chloride, $C_{12}H_{17}N_4OSCl$.

Thiamin chloride (**1a**)

Thiamin is used chiefly in the form of its chloride hydrochloride (**1b**) [*67-03-8*] and nitrate (**1c**) [*532-43-4*].

Thiamin chloride hydrochloride (**1b**)

Thiamin nitrate (**1c**)

6.2. History

The history of the discovery of thiamin is closely associated with beriberi, a disease prevalent in many parts of the world where the diet consisted mainly of milled or polished rice. The first "cure" was obtained by TAKAKI, then surgeon general of the Japanese Navy, who suggested that the patients should reduce their carbon/nitrogen intake ratio by increasing their protein intake with a "Western-style" diet [506]. In the 1890s the Dutch physician EIJKMAN noticed by chance that hens kept on a diet of dehusked rice developed a disease very similar to human beriberi [507], and that adding rice bran to the feed could prevent it. He thus postulated that beriberi was caused not by a pathogen or by noxious agents in the food, but by the lack of a vitally important food constituent. However, this conclusion was firmly established only in 1901 by GRIJN who showed that this "polyneuritis preventive factor" was destroyed in meat or bran by heat [508].

GRIJN extracted the factor from rice bran, showing that it was water soluble. The pure factor was isolated from rice bran by FUNK, who obtained a crystalline substance that prevented beriberi [509]. Having found that the substance had the character of an amine, he coined the term "vitamin" (vitally important amine). Pure crystals of thiamin hydrochloride were isolated from rice bran extracts in 1926 by Dutch chemists JANSEN and DONATH [510] who, however, omitted the sulfur atom in the formula they published, delaying elucidation of the chemical structure of vitamin B_1 [511]. This was achieved in 1936, independently by WILLIAMS [512,513] and GREWE [514], who discovered that the molecule could be split quantitatively by sulfite into a 6-aminopyrimidinesulfonic acid (**2b**) and a thiazole ring (**3a**) (see section 6.4).

Confirmation of the structure of thiamin was obtained by WILLIAMS who accomplished the first total synthesis by building up each ring independently and then linking the two together [515]. The synthetic product was shown to be identical to the natural compound by its UV spectrum and biological tests on microorganisms and animals. In 1937 TODD and BERGEL synthesized thiamin by a different approach [516,517], soon followed by ANDERSAG and WESTPHAL [518].

Industrial production was started in 1937 by Hoffmann-La Roche in Switzerland and Merck in the United States. Demand and production rose rapidly.

6.3. Physical Properties

Thiamin chloride hydrochloride (**1b**) $C_{12}H_{18}N_4OSCl_2$ is a white crystalline material, *mp* 248 – 250 °C (decomp.). It crystallizes as colorless monoclinic needles. It has a characteristic odor and a slightly bitter taste. It is soluble in water (1 g/mL) and glycerin (1 g/18 mL), sparingly soluble in alcohol or acetone, and almost insoluble in other organic solvents. On exposure to air of average humidity, dry thiamin is converted to the hydrate by water absorption (up to 4 wt %). The water can be removed by heating at 100 °C, or under vacuum over conventional drying agents. If protected from light and humidity, thiamin is relatively stable against air oxidation, even on heating.

Thiamin nitrate (**1c**) $C_{12}H_{17}N_5O_4S$ is a white crystalline material with *mp* 190 – 200 °C (with decomposition). It shows weak solubility in water (about 2.7 g per 100 mL).

The UV spectrum of thiamin chloride hydrochloride (**1b**) in aqueous solution shows maxima at 234 nm ($\varepsilon_1 = 307$) and 266 nm ($\varepsilon_1 = 277$) [519, 520]. Its IR spectrum in KBr is reported in [521].

The ^{1}H NMR spectrum of thiamin chloride hydrochloride (**1b**) in D_2O is reported in [522], and the ^{13}C and ^{15}N NMR spectra in [523–525].

Since the mass spectrum of thiamin chloride hydrochloride (**1b**) shows no molecular ion under standard EI conditions, literature refers to data obtained using the fast atom bombardment technique [526–528].

X-ray crystallographic data [529] and molecular orbital calculations of the electron density [530] have also been published.

6.4. Chemical Properties

Hydrolysis. Under mildly alkaline aqueous conditions (at pH 7.0 or above), thiamin is converted to the thiol form (**4**) (Fig. 5). The rate-limiting step appears to be ring opening [520, 531,532].

A 5 % aqueous solution of the hydrochloride (**1b**) has pH ca. 3.5, whereas the corresponding solution of the nitrate (**1c**) has pH 6.5 – 7.1.

Under normal conditions, an aqueous solution of thiamin is stable below pH 5.5, even to oxidation, but decomposes to (4-amino-2-methyl-5-pyrimidinyl)methanol (**2a**) [*73-67-6*] and 4-methyl-5-(2-hydroxyethyl)thiazole (**3a**) [*137-00-8*] when heated in a sealed tube at 140 °C (Fig. 5) [533].

By treatment with sulfite in weakly acidic solutions, thiamin chloride (**1a**) is split into the methanesulfonate derivative (**2b**) and the thiazole compound (**3a**) (Fig. 5) [511,512]. Under strongly acidic conditions, thiamin chloride (**1a**) is converted to oxythiamin (**5**), which has no vitamin activity (Fig. 5).

Various aspects of the chemistry of thiamin are still under investigation, especially the reversible opening of the thiazole ring in aqueous alkaline solution [528,534–537].

Intramolecular Aminolysis. Under strongly basic, but anhydrous conditions (2 mol of sodium ethoxide in ethanol), the 4′-amino group of thiamin adds to the thiazole ring to give tricyclic dihydrothiochrome (**6**), which then eliminates a thiolate ion to give the sodium salt of the yellow form of thiamin (**7**) [531, 538–540]. Addition of acid converts **7** to the thermodynamically more stable thiol form (**4**) (Fig. 6).

Oxidation. In the presence of an oxidant, the thiolate (**7**) is irreversibly converted to thiochrome (**8**) (Fig. 6). Thiochrome (**8**) is a yellow crystalline compound which has been isolated from yeast but has no physiological importance. In solution it exhibits a strong blue fluorescence, a property used for the quantitative determination of thiamin (see Section 6.11). Reduction of thiochrome (**8**) converts it back to thiamin, in up to 60 % yield.

Ylid Formation. Upon abstraction of the hydrogen atom from the 2-position of the thiazole ring, the ylid of thiamin (**9**) is formed (Fig. 6), which plays a central role in both the coenzymatic reaction of vitamin B_1 as well as in nonenzymatic reactions such as the acyloin condensation. The ability of thiamin to form an ylid can be rationalized in terms of molecular orbital theory and resonance structures [534, 541]. There is, however, widespread disagreement about whether the 4′-amino group acts as an intramolecular acid or base in either the chemistry or the enzymology of ylid formation from thiamin. Isolation of the ylid in the solid state after deprotonation of thiamin chloride with one equivalent of sodium ethoxide has been the subject of much controversy [531,534], the tricyclic structure (**6**) being favored over a tetracyclic one, based on NMR studies. Kinetic and thermodynamic studies have been made to interpret the lability of the 2-proton in the thiazole ring of thiamin [542–544].

The pK_a of thiamin in aqueous solution at 25 °C is estimated at 12.6 for the CH in the thiazole ring and 4.8 for the NH_2 of the pyrimidine moiety [531,541].

Reduction. Thiamin undergoes reduction of the thiazole ring by a variety of reducing agents (lithium aluminum hydride, sodium borohydride, etc.) to afford, via the intermediate dihydrothiamin (**10**), tetrahydrothiamin (**11**) [545, 546] (Fig. 7).

6.5. Natural Occurrence and Isolation

Thiamin is widespread in nature, but only in relatively small quantities [547–549].

Average thiamin concentrations in foodstuffs (in μg/100 g) are as follows:

Wheat germ	2050
Brewer's yeast, dried	1820
Soyabeans	1300
Dried beans and peas	680

Figure 5. Reactions of thiamin chloride (**1a**)

Nuts	300 – 560
Rice, brown	300
Rice, white	50
Potatoes	170
Beef heart	600
Beef liver	300
Pork	600 – 950
Milk whey, dried	500
Whole milk	30 – 70
Eggs	70
Fish	50 – 90
Vegetables (flower and fruit)	70
Vegetables (leaf and stem)	70
Vegetables (root and tuber)	60

Thiamin can be found in animal tissue in phosphorylated forms, mainly as the pyrophosphate (**12b**) [*154-87-0*] (see section 6.9), where it is bound to an enzyme as a protein complex. The heart, liver, kidney, and the brain are organs with a high thiamin concentration of ca. 100 mg/100 g. Normal human blood contains ca. 90 ng of thiamin per liter, although there are strong variations among individuals, with 49 ng/L being considered as indicative of a possible deficiency.

In plant products, free thiamin is the most abundant form. It is found in the pericarp and the seeds of grains, cereal grains, yeast, dried vegetables, rice, and potatoes. Oils, fats, and highly processed foods such as refined sugars are essentially devoid of thiamin.

Although thiamin is widespread in foodstuffs, its concentration in individual foods varies widely and is relatively low since considerable amounts are destroyed in cooking, either by heat, the presence of metals, chlorine in water, or by reactive organic substances. Therefore, to restore the nutritional quality of processed foods to the original or acceptable levels, they have to be supplemented with synthetic thiamin or its derivatives. Thus in developed countries most white rice and white flour are fortified with vitamin B_1. Since extraction of thiamin from natural sources would not be economically profitable, it has to be manufactured by chemical synthesis.

Figure 6. Reactions of thiamin chloride (**1a**)

Figure 7. Reduction of thiamin

6.6. Biosynthesis in Microorganisms

Thiamin pyrophosphate (**12b**) is synthesized in prokaryotic and eukaryotic microorganisms from the precursor compounds hydroxymethylpyrimidine (**2a**) and hydroxyethylthiazole (**3a**). The biosynthetic pathways leading to these precursor compounds are different in facultative anaerobic bacteria, e.g., *Escherichia coli* or *Salmonella typhimurium*, and in lower eu-

karyotes such as *Saccharomyces cerevisiae* or *Schizosaccharomyces pombe*. Reviews covering thiamin biosynthesis up to the mid-1980s can be found in [550, 551]. The latter is restricted to *E. coli* and *S. typhimurium*.

6.6.1. Biosynthesis of the Pyrimidine Component in Prokaryotes

One of the key findings revealing the origin of the pyrimidine component (**2a**) of thiamin in prokaryotes was the observation that certain mutants of *S. typhimurium* defective in one of the early steps of purine biosynthesis were thiamin auxotroph as well [552–555].

Specifically, mutants defective for conversion of phosphoribosyl pyrophosphate (PRPP) to phosphoribosyl aminoimidazole (**13**) (AIR) (e.g., *purF* mutants) required thiamin supplementation in addition to purine nucleotides for growth (Fig. 8). Purine mutants impaired in conversion of AIR (**13**) to inosine monophosphate (IMP), however, were independent of exogenous thiamin supply. These and other observations [550, 551] suggested that purine nucleotide and thiamin biosynthesis use the same route up to production of AIR (**13**). Conversion of AIR (**13**) to the pyrimidine component (**2a**) is a complex intramolecular rearrangement, which in *E. coli* depends on the *thiC* gene product (see below).

Additional pathways to the pyrimidine component (**2a**) in *S. typhimurium*, independent of *purF*, have been suggested [556–558].

6.6.2. Biosynthesis of the Pyrimidine Component in Eukaryotes

An initial indication that bacteria and yeast employ different biosynthetic pathways to the pyrimidine component (**2a**) of thiamin was the finding that in yeast cultivated with ^{14}C-labelled formate the ^{14}C atom was recovered at the C4 position of the pyrimidine component (**2a**) [559].

In contrast, the pyrimidine component from ^{14}C-formate-fed prokaryotes contained the ^{14}C label in the C2 position. Feeding of *S. cerevisiae* with ^{14}C- or ^{15}N-labelled histidine resulted in nonrandomly labelled thiamin [560, 561] and indicated that N3, C4, and the amino nitrogen N9 of the pyrimidine moiety (**2a**) were derived as a unit from the N – C – N part of the imidazole ring of histidine. The amino nitrogen of histidine was not incorporated. The source of C2, C5, C6, the methoxy C7, and the methyl C8 atom of the pyrimidine component (**2a**) was ribose [562–564]. A minor pathway to the pyrimidine component (**2a**) in eukaryotes has been suggested in which the single carbon atom of formate is incorporated into the C2 position. This pathway, however, is not identical to the hydroxymethylpyrimidine biosynthesis pathway in prokaryotes [562].

6.6.3. Biosynthesis of the Thiazole Component

Cysteine is the common sulfur source for biosynthesis of the thiazole component (**3c**) of thiamin [565]. In yeasts the N and C2 atoms are obtained from glycine (Fig. 9) [566, 567]. In the yeast *Candida* the source of the C4 to C8 atoms is ribulose-5-P (**14**) derived from the oxidative branch of the pentose phosphate pathway [568]. In *S. cerevisiae* the pentose contributing C5 to C8 of the thiazole component (**3c**) is derived from the oxidative and nonoxidative branches of the pentose phosphate pathway to a similar extent [569, 570].

In facultative anaerobic bacteria such as *E. coli* and *S. typhimurium* the C2 and N atoms of the thiazole component (**3c**) are derived from the α-carbon and nitrogen atom of tyrosine (Fig. 10) [571–573]. The C_5 sugar D-1-deoxyxylulose (**15**), derived from the glycolysis intermediates pyruvate and glyceraldehyde-3-phosphate, serves as donor for the C4 to C8 carbon atoms of the thiazole moiety (**3c**) [574].

In aerobic bacteria such as *B. subtilis* the C2 and N atoms of the thiazole component (**3c**) are derived from glycine, as in yeasts [575].

Figure 8. Biosynthesis of the pyrimidine component in prokaryotes

Figure 9. Biosynthesis of the thiazole component in yeasts

6.6.4. Biosynthesis of Thiamin Pyrophosphate

Biosynthesis of thiamin pyrophosphate (**12b**) from the pyrimidine (**2a**) and thiazole (**3a**) precursors (Fig. 11) depends on the activity of five enzymes, four of which are kinases. Hydroxymethylpyrimidine kinase and phosphomethylpyrimidine kinase convert pyrimidine component (**2a**) to the mono- (**2c**) and diphosphorylated (**2d**) derivatives, respectively. The enzymes have been purified from yeast [576,577]. Hydroxyethylthiazole kinase catalyzes phosphorylation of the thiazole component (**3a**) to the phosphorylated derivative (**3c**). An *S. cerevisiae* mutant defective for this enzyme grew well on minimal medium without thiamin supplementation [578]. It was concluded that in yeast, hydroxyethylthiazole kinase is not required for de novo synthesis of thiamin but seems to be involved in a salvage pathway of thiamin biosynthesis using preformed hydroxyethylthiazole (**3a**). The coupling enzyme thiamin phosphate synthase has been purified from *S. cerevisiae* and partially purified from *E. coli* [579,580]. Hydroxyethylthiazole kinase and thiamin phosphate synthase of *S. cerevisiae* mapped in the same gene, and the two enzymatic activities could not be separated during purification to apparent homogeneity. This finding indicated a bifunctional enzyme in the thiamin pyrophosphate biosynthetic pathway of yeast [581].

Figure 10. Biosynthesis of the thiazole component in facultative anaerobic bacteria

Figure 11. Biosynthesis of thiamin pyrophosphate

In *E. coli*, thiamin monophosphate (**12a**) can be derived from exogenous thiamin (**1a**) by means of the enzyme thiamin kinase. Conversion of thiamin monophosphate to the active coenzyme thiamin pyrophosphate (**12b**) is catalyzed by thiamin monophosphate kinase. In yeasts and many other organisms, including humans (for references, see [582]), thiamin pyrophosphate (**12b**) can be obtained from exogenous thiamin (**1a**) by a one-step phosphorylation reaction catalyzed by thiamin pyrophosphokinase.

6.6.5. Thiamin Biosynthetic Genes from *E. coli*

A number of mutations leading to thiamin auxotrophy in *E. coli* (*thi* mutants) mapped at 90′ of the *E. coli* chromosome [583,584]. A 6.5 kilobase genomic DNA fragment was isolated from *E. coli* that complemented all of the mutations clustered in the 90′ *thi* locus [585]. Five tightly linked open-reading frames, designated as *thiC, thiE, thiF, thiG* and *thiH* were identified. To evaluate the function of the genes encoded by these open-reading frames mutants were constructed, each of them carrying another defect in one of the five open-reading frames. The growth requirements of these mutants indicated that the *thiC* gene product catalyzes an essential step in biosynthesis of the pyrimidine component (**2a**) of thiamin from 5-aminoimidazole ribonucleotide (**13**) (AIR) (see Section 6.6.1). The *thiE, thiF, thiG* and *thiH* mutants responded to thiazole (**3a**), but not to D-1-deoxyxylulose (**15**), indicating that the *thiE, thiF, thiG*, and *thiH* genes are involved in synthesis of the thiazole component (**3a**) from the precursor compounds tyrosine, cysteine, and D-1-deoxyxylulose (**15**) (see Fig. 10).

The *thiG* gene exhibits significant homology to the *chlN* gene of *E. coli* [586], encoding an enzyme of the molybdopterin biosynthetic pathway [587]. Molybdopterin complexed with a Mo atom is the cofactor of Mo-containing enzymes, e.g., respiratory chain nitrate reductase, formate dehydrogenase, or biotin-D-sulfoxide reductase [588, and references therein]. Molybdopterin, like the thiazole component (**3a**) of thiamin, contains a sulfur atom, suggesting a role of the *chlN* and the *thiG* gene products in sulfur incorporation into molybdopterin and into the thiazole component (**3a**), respectively.

The kinases encoded by *thiD, thiM, thiL* and *thiK*, which are involved in thiamin pyrophosphate biosynthesis from the pyrimidine (**2a**) and thiazole component (**3a**) or from thiamin (**1a**) (see Fig. 11), have been mapped on the *E. coli* chromosome [589,590].

The *nuvC* gene located at 45′ of the *E. coli* chromosome was found to be involved in thiamin pyrophosphate biosynthesis, as well [591]. The *nuvC* gene product is one of the two enzymes, designated factors A and C, responsible for modification of the uridine moiety of certain tRNAs with sulfur. *E. coli nuvC* mutants lacking factor C were found to be thiamin auxotroph in addition to being unable to produce 4-thiouridine. The mutations could be complemented by administration of hydroxyethylthiazole (**3a**). One could speculate that factor C, which transfers the sulfur atom from cysteine to tRNA uridine to form 4-thiouridine, is also responsible for delivering a sulfur atom from cysteine to the thiazole component (**3a**).

6.6.6. Mapping and Cloning of Thiamin Biosynthetic Genes from Other Species

Thi genes complementing *thiA32* (hydroxyethylthiazole (**3a**) requirement), *thiC34* (hydroxymethylpyrimidine (**2a**) requirement) and to some extent *thiB33* mutations (coupling defect) of *E. coli* mutants have been mapped on the second symbiotic megaplasmid of *Rhizobium meliloti* [592].

Three classes of *B. subtilis thi* mutants can be distinguished according to the dependence on hydroxymethylpyrimidine (**2a**) (*thiA* mutants), hydroxyethylthiazole (**3a**) (*thiB* mutants) or thiamin (*thiC* mutants) for growth [593]. (Note that the nomenclature of *thi* mutants in *B. subtilis* and *E. coli* is not consistent.) Whereas in *E. coli* the genes involved in biosynthesis of the two thiamin precursor components and the coupling enzyme are tightly clustered, the *thiA*, *-B*, and *-C* mutations of *B. subtilis* mapped at 70°, 102°, and 331° of the bacterial chromosome, respectively [594]. During the course of the *Bacillus subtilis* genome sequencing project a 97 kb region from 325° to 333° including the *thiC* locus has been cloned and sequenced [595].

Schizosaccharomyces pombe thi2 mutants required hydroxyethylthiazole (**3a**) for growth. The *thi3* and *thi4* mutants could be complemented with hydroxymethylpyrimidine (**2a**) and thiamin (**1a**), respectively [596]. The *thi3* gene, which is identical to the *nmt1* gene [597], has been isolated and sequenced. The *thi2* gene has been cloned [598], but the sequence has not been published so far. The thiamin biosynthetic *nmt2* gene of *Schizosaccharomyces pombe* has been cloned and sequenced [599]. The *thi4* gene [600], which should be involved in phosphorylation of one of the two thiamin precursor components or in the coupling step, has some

weak homology to the *E. coli thiE* gene, which is required for biosynthesis of the thiazole component (**3a**). There was no further sequence homology observed between the *thi* genes of *E. coli* and *Schizosaccharomyces pombe* in accordance with the different biochemical routes leading to thiamin pyrophosphate (**12b**) in yeast and bacteria. Recently the DNA sequence of the *thi80* gene encoding thiamin pyrophosphate kinase from yeast has been reported [582].

6.6.7. Regulation of Thiamin Biosynthesis in Prokaryotes

Thiamin biosynthesis is tightly controlled by feedback and repression mechanisms. In *S. typhimurium*, thiamin, which has no effect on PRPP aminotransferase, interfered with biosynthesis of pyrimidine (**2a**) and thiazole component (**3a**) at 40 ng/mg dry cell weight, and with the coupling reaction at 100 ng/mg dry cell weight [601,602]. In addition, hydroxyethylthiazole (**3a**) inhibited its own synthesis at 1 ng/mg dry cell weight, whereas hydroxymethylpyrimidine (**2a**) did not interfere with its own synthesis.

The hydroxymethyl- and phosphomethylpyrimidine kinases, hydroxyethylthiazole kinase, and the coupling enzyme thiamin phosphate synthase (see Section 6.6.4) are repressed in *E. coli* by intracellular thiamin [584,603,604]. Mutant *E. coli* strains resistant towards the thiamin antimetabolite pyrithiamin exhibited similar activities of the coupling enzyme and hydroxyethylthiazole kinase, irrespective of the intracellular thiamin concentration. The mutation in one of these strains, designated *PT-R1*, mapped at 90′ of the *E. coli* genome and is probably very close to the *E. coli thi* locus.

6.6.8. Regulation of Thiamin Biosynthesis in Yeasts

In *S. cerevisiae* two positive regulatory genes of thiamin biosynthesis have been described and cloned [605–607]. These genes were designated *thi2* (*pho6*) and *thi3* similar to the structural *thi* genes of *S. pombe*. Mutations in *S. cerevisiae thi2* and *thi3* resulted in thiamin auxotrophy and affected synthesis of thiamin monophosphate (**12a**) from the pyrimidine (**2a**) and thiazole component (**3a**). In addition, *thi3* mutants had a markedly impaired thiamin transport system.

As in *S. typhimurium* and *S. cerevisiae*, biosynthesis of thiamin is negatively regulated in *S. pombe* by thiamin [596]. Expression of the thiamin biosynthetic genes *thi2* and *thi3* involved in biosynthesis of the thiazole (**3a**) and pyrimidine (**2a**) components in *S. pombe*, respectively (see Section 6.6.6), is strongly repressed by thiamin [598]. In addition, the *thi2* gene is repressed by hydroxyethylthiazole (**3a**), but not by hydroxymethylpyrimidine (**2a**), similar to the situation in *S. typhimurium*. Several mutations designated *tnr*1, 2, and 3 have been mapped in the genome of *S. pombe*, resulting in de-repressed expression of genes involved in thiamin biosynthesis [608]. Intracellular levels of thiamin (**1a**), but not of thiamin monophosphate (**12a**) or thiamin pyrophosphate (**12b**), in *tnr*3 were 10- to 20-fold higher (ca. 10 ng/mg dried cells) than in *tnr*1, 2 or in the wildtype. In addition to mutations in the *tnr* genes that might encode negative regulators of thiamin biosynthesis, a positive regulatory gene designated *thi1* has also been identified in *S. pombe*. *Thi1* mutants are thiamin auxotroph. They can be complemented with hydroxyethylthiazole (**3a**), but not with hydroxymethylpyrimidine (**2a**), indicating that these mutants can not produce the thiazole component (**3a**). Accordingly, no *thi2* mRNA encoding a structural gene of thiazole biosynthesis could be detected in *S. pombe thi1* mutant strains.

6.6.9. Thiamin-Overexpressing Microorganisms

E. coli PT-R1 mutants which are deregulated for thiamin biosynthesis (Section 6.6.7) accumulated ca. 100 ng thiamin/mg dry cellular weight [584], which corresponded to a three- to fourfold increase of thiamin levels compared to wildtype *E. coli* strains. Similar levels of thiamin pyrophosphate (**12b**) were reached in *S. typhimurium* 1.5 h after derepression of thiamin biosynthesis caused by adenosine preincubation [602]. An *S. typhimurium thi* mutant defective in thiazole biosynthesis accumulated hydroxymethylpyrimidine (**2a**) in the medium.

Certain *Neurospora crassa* mutants containing a defect in biosynthesis of the thiazole component (**3a**) secreted up to 0.2 mg/L of substances closely related to the pyrimidine component (**2a**) into the culture broth. The chemical nature of one of them was identified as being the diamine (**2e**) [609, 610]. A broad search among many yeast species has been reported [611]. The *Saccharomyces cerevisiae* strain 1271 secreted up to 200 mg/L thiamin into the culture broth.

6.7. Chemical Synthesis

Several syntheses of thiamin (**1**) have been published, and basically two general methods have evolved over the years [612–616].

6.7.1. Condensation of the Pyrimidine and Thiazole Rings

The first approach, developed after the original method reported by WILLIAMS et al. [514], consists of separate syntheses of 4-amino-5-bromomethyl-2-methylpyrimidine hydrobromide (**2f**) [*2908-71-6*] and of the thiazole moiety (**3a**) or its acetate (**3b**) [*656-53-1*]. Condensation of the two intermediate heterocycles gives thiamin bromide hydrobromide [*4234-86-0*] (**1d**) which is converted to thiamin chloride hydrochloride (**1b**) by treatment with silver chloride in methanol or with an ion-exchange resin.

Thiamin bromide hydrobromide (**1d**)

The first industrial synthesis of vitamin B_1, developed by Merck-Rahway (United States), followed this synthetic route.

6.7.2. Construction of the Thiazole Ring on a Preformed Pyrimidine Portion

The second general method, based on the procedure of TODD and BERGELL [516, 517] and ANDERSAG and WESTPHAL [518], constructs the thiazole ring on a preformed pyrimidine intermediate. Thiamin manufacturers generally follow this approach. Some use malonitrile [*109-77-3*] as the starting material for construction of the 4-amino-5-aminomethyl-2-methylpyrimidine ring (**2e**) [*95-02-3*] (also called Grewe diamine). Others start with acrylonitrile but all proceed via the key Grewe diamine intermediate (**2e**) through to thiothiamin [*299-35-4*] (**16**) (see page 82).

For the preparation of malonitrile, β-aminopropionitrile (**17a**), obtained by addition of ammonia to acrylonitrile, is subjected to oxidative dehydrogenation in the gas phase at high temperature and in the presence of molecular oxygen and a metallic catalyst [617].

Pyrimidine Moiety. A convenient synthesis of the pyrimidine moiety starts from acetamidine hydrochloride [*124-42-5*] or the corresponding imino ether and a suitably substituted C_4 unit carrying the required functional groups, such as methoxymethylenemalononitrile [*672-25-3*] (**18a**), aminomethylenemalononitrile [*672-81-1*] (**18b**), 2-dimethoxymethyl-3-methoxypropionitrile (**19**), or α-amino-β-formylaminopropionitrile (**20**) (aniline, *o*-chloroaniline or *N*-methylaniline are the most frequently used α-amino groups).

Subsequent conversion of the resulting intermediates – 5-cyanopyrimidine [*698-29-3*] (**21a**), *N*-[(4-amino-2-methyl-5-pyrimidinyl)-methyl]-acetamide [*23676-63-3*] (**2g**), *N*-[(4-amino-2-methyl-5-pyrimidinyl)-methyl]-form-

amide (**2h**) – provides the desired Grewe diamine (**2e**) [613, 618–623].

21a: R = CN
21b: R = CH(OMe)$_2$
21c: R = CHO

20a: R$_1$ = H R$_2$ = H

2h: R = NHCHO
2i: R = NHCHS

The Takeda and Ube in Japan have jointly developed a new process to prepare the key intermediate Grewe diamine (**2e**) [624, 625]. Acrylonitrile and carbon monoxide are used as basic raw materials. Nitrite-catalyzed oxidation of acrylonitrile in the presence of an alcohol affords 3,3-alkoxypropanenitrile (**22**). This same intermediate can also be obtained, probably more expensively, by formylation of acetonitrile, followed by acid-catalyzed acetalization [626, 627]. Alternatively, **22** can be generated by electrooxidation of β-aminopropionitrile (**17b**) [628].

22: R = Me or Bu

23: R = Me or Bu

Carbonylation of dialkoxypropanenitrile (**22**) followed by acid-catalyzed acetalization and subsequent thermal elimination of alcohol yields 2-(dialkoxymethyl)-3-alkoxy-2-propenenitrile (**23**). On reaction with acetamidine, **23** gives in high yield the acetal (**21b**), which after hydrolysis to the 2-methyl-4-amino-5-pyrimidinecarboxaldehyde [*73-68-7*] (**21c**) and reductive amination provides the desired Grewe diamine (**2e**) [629–631].

In a different approach [632], 5-cyano-1,6-dihydropyrimidine (**25**), prepared by Thorpe–Ziegler cyclization of N'-cyano-N-(2-cyanoethyl)-acetamidine (**24**), is converted directly to the desired Grewe diamine (**2e**) by dehydrogenation in the presence of Raney cobalt and ammonia.

24

25

Thiamin Synthesis. Having obtained 4-amino-5-aminomethyl-2-methylpyrimidine (**2e**), three chemical steps are still required to obtain thiamin (**1a**): extension of the aminomethyl side chain at the 5-position, cyclization to the thiazole ring, and conversion to thiamin. Commonly used synthons for extending the side chain are 3-chloro-5-hydroxypentan-2-one [*13045-13-1*] (**26a**), the 3-mercaptoketone [*15678-01-0*] (**26b**) or their corresponding acetates [*13051-49-5*] (**26c**) and [*55289-66-2*] (**26d**) [633, 634]. Besides the multistep preparation of chloroketone (**26c**), a catalytic procedure has been developed in which a mixture of α-chloroacetylacetone (**27**) and ethylene oxide is reacted at 80 °C in an autoclave in the presence of nickel(II) acetylacetonate as catalyst [635].

26a: R$_1$ = Cl, R$_2$ = H
26b: R$_1$ = SH, R$_2$ = H
26c: R$_1$ = Cl, R$_2$ = C(O)CH$_3$
26d: R$_1$ = SH, R$_2$ = C(O)CH$_3$

27

Condensation of 4-amino-5-aminomethyl-2-methylpyrimidine (**2e**) with carbon disulfide and chloropentanone (**26a**) provides in very good yield the dithiocarbamate (**28**), which is then converted by acidic treatment to the 4-thiazoline-2-thione derivative (**16**) [636–639]. Oxidative desulfurization with hydrogen peroxide followed by anion-exchange resin completes the synthesis of thiamin hydrochloride (**1a**).

28

16

Similarly, thiamin hydrochloride (**1b**) can be prepared by condensation of *N*-[(4-amino-2-methyl-5-pyrimidinyl)methyl]methanethioamide (**2i**) [*31375-20-9*], or *N*-formyl Grewe diamine (**2h**) with ester (**26c**) or (**26d**), respectively [633,634,640]. Reaction of Grewe diamine (**2e**) with α-mercaptoketone (**26b**) and formaldehyde provides dihydrothiamin (**10**) which can then be converted to thiamin (**1a**) [641,642].

A more convergent synthesis of thiamin (**1b**) has been developed by Hoffmann-La Roche [643,644]. Condensation of 3,4-dihydro-7-methylpyrimido[4,5-*d*]pyrimidine (**29**) [*31375-19-6*] with the mercaptopentanone (**26d**) in formic acid followed by treatment with hydrochloric acid gave thiamin in high yield. **29** is obtained by heating Grewe diamine (**2e**) in dimethylformamide dimethyl acetal [645–647] or alternatively, in an excess of triethyl orthoformate with a catalytic amount of *p*-toluenesulfonic acid.

29

6.8. Commercial Forms

The commercially available forms of thiamin are the chloride hydrochloride (known as thiamin hydrochloride) (**1b**) and the mononitrate (**1c**). World production of thiamin in 1993 was estimated at ca. 4200 t; the principal producers are Hoffmann-La Roche, Takeda Chemical Industries, and Chinese State Companies. The price for thiamin in 1993 on the U.S. market was ca. $ 30 – 35/kg.

The discovery in 1951 by Fujiwara et al. [648] that treatment of thiamin with an extract of garlic or other *Allium* species converts it to a product that is physiologically very active opened the door to derivatives of thiamin that act as "prodrugs." The mixed thiamin allyl disulfide, TAD, (**30a**) (allithiamin [*554-44-9*]) was the first representative of a variety of thiamin alkyl sulfides. The most important commercial forms, almost exclusively marketed in Japan (they are not yet approved in the United States) are TAD, thiamin propyl disulfide, TPD, (**30b**) (prosulthiamin [*59-58-5*]), thiamin tetrahydrofurfuryl disulfide (**30c**) (fursulthiamin [*804-30-8*]), *O*-benzoylthiamin disulfide (**31**) (bisbenthiamin [*2667-89-2*]), and dibenzoylthiamin [*299-88-7*] (**32**). These forms are more stable, less water soluble and more lipid soluble, being thus more rapidly absorbed and better retained in the body than the more common thiamin hydrochloride. In vivo they are converted back to thiamin [649].

31: R = benzoyl

Dibenzoylthiamin (**32**)

6.9. Derivatives, Analogues, and Antimetabolites

Thiamin forms esters at the hydroxyethyl side chain with various acids, the most important being the mono- (**12a**), di- (**12b**), and triphosphates (**12c**). The pyrophosphate (**12b**) acts as a coenzyme (cocarboxylase) in the decarboxylation of α-keto acids in association with carbohydrate metabolism. The palmitate (**33**) is as effective as thiamin and is used for supplementation of various feed and food products due to its stability and good lipid solubility [650].

In Japan, derivatives of thiamin with sugars, especially with saccharide, have also been prepared as food additives. They are readily hydro-

lyzed to physiologically active thiamin and, unlike thiamin, have no unpleasant smell.

Other derivatives are obtained from the thiol form of thiamin (see Section 6.8).

Several analogues have been synthesized by structural modification of the pyrimidine or thiazole ring, but none exceeds the biological activity of thiamin. The 2-ethyl analogue (**34**) shows activity comparable to that of thiamin, whereas the 2-butyl (**35**), 2-methoxy (**36**), and 2-methylthio (**37**) analogues are potent antagonists [651–653].

Replacement of the 4-amino group by hydrogen or an alkylamino group generally results in loss of activity [652,654]. Oxythiamin (**5**) (see section 6.4), the 4-hydroxy (or 4-oxo) analogue is a known antagonist.

From analogues **38** and **39** it was concluded that the nitrogen atom in the 1-position is more important for coenzyme activity than that at the 3-position [655,656].

Compounds **40** and **41** [657], the 2-methyl substituted analogue **42** [658], oxothiamin (**43**) and thiothiamin (**16**) are completely inactive [659–661], whereas the homothiaminglycol (**44**) is an antagonist [662], demonstrating that hydrogen at the 2-position and the 3-hydroxyethyl group at the 5-position in the thiazole ring are essential for biochemical activity.

Replacement of the thiazole ring by other heterocycles, as in imidazolthiamin (**45**) [652,663], pyrithiamin (**46**) [659,664,665] or Amprolium (**47**) [666] provides potent thiamin antagonists. The latter is a good inhibitor of thiamin diphosphate dependent enzymes. In small doses, it affects thiamin transport across bacterial cell walls and is therefore an effective coccidiostat. It is used commercially for the treatment of poultry [667,668].

Pyrithiamin (**46**)

Amprolium (**47**)

6.10. Biochemical and Physiological Functions

6.10.1. Metabolic Functions in the Organism

Thiamin serves a number of essential metabolic functions and its deficiency is associated with imbalances in carbohydrate status, with consequent deleterious effects on nerve functions. In living systems, the only known biologically active form of thiamin is the diphosphate ester (**12b**) – otherwise known as thiamin pyrophosphate, TPP, or cocarboxylase – which is formed by the reaction between thiamin and ATP in liver cells [669]. As a cofactor of enzymes in intermediate metabolism, TPP participates in the decarboxylation of α-keto acids (pyruvate and α-ketoglutarate dehydrogenase complex) and in the reversible α-ketol transfer reactions catalyzed by transketolase in the pentose phosphate cycle [670, 671].

Oxidative Decarboxylation. Pyruvate is an important intermediate product of glycolysis, a largely anaerobic process. Under these conditions, pyruvate is decarboxylated to acetyl-coenzyme A (acetyl-CoA), a universal product of the metabolism of carbohydrates, fats, and amino acids. The decarboxylation reactions are initiated by addition of pyruvic acid to the 2-position of the thiazole ylid (**9**) of TPP to form the adduct (**48a**). The adduct after the splitting-off of carbon dioxide forms the so-called active aldehyde (**49**) from which the subsequent biochemical reactions are derived, leading ultimately to acetyl-coenzyme A [672] (see bottom of page).

To support this mechanism, the protonated form of the adduct between thiamin and acetaldehyde – 2-(1-hydroxyethyl)thiamin (**50**) – has been synthesized [673] as well as the thiamin – pyruvate adduct and its pyrophosphate (**48b**) [674, 675].

50

In the citric acid cycle, TPP similarly takes part in the oxidative decarboxylation of α-ketoglutaric acid to succinyl coenzyme A. Analogously, the oxidative decarboxylation of the threebranched-chain α-ketoacids derived from the deamination of leucine, isoleucine, and valine is catalyzed by TPP among a multienzyme complex.

Transketolase Reactions. In the transketolase reactions (direct glucose oxidation), TPP adds to appropriate α-ketosugars to break the carbon – carbon bond between C2 and C3 to

form an active intermediate which is then transferred to a suitable acceptor. This metabolic pathway is important for the production of pentoses for RNA and DNA synthesis.

Other Functions. Thiamin may be an active substance in the nervous system. It has been postulated that thiamin, probably as thiamin triphosphate (**12c**), could play an essential role in the stimulation of peripheral nerves [676–678].

This could be a distinct function of thiamin, independent from its role as a coenzyme in the metabolism of carbohydrates. This remains, however, to be established.

6.10.2. Thiamin Requirements and Deficiency

The maintenance requirements for thiamin depend on carbohydrate intake. An average figure of 20 – 30 µg per kilogram body weight is given for humans. This corresponds to a recommended daily allowance ranging from 0.3 to 1.5 mg/d, depending on age and sex; this recommendation differs from country to country. Factors such as pregnancy, lactation, fever, alcoholism, liver disease, stress, or dietary practices can substantially raise the minimum requirement.

Beriberi is the most prominent pathological condition resulting from a thiamin deficiency. Symptoms of the disease can vary, depending on individual, diet, duration and severity of the deficiency. The disorders affect the central nervous system, but are also accompanied by cardiovascular damage.

In most cases, parenteral administration of thiamin in large doses is sufficient to restore the normal supply status of thiamin. For better absorption from the digestive organs, derivatives of the thiol form of thiamin are used in Japan (see Section 6.8).

6.11. Analytical Methods

For the determination of thiamin in foods, feeds, pharmaceutical preparations and other substances, physicochemical [679, 680] and microbiological [680] methods are employed.

Since thiamin occurs principally as phosphate esters and a significant part is therefore protein bound, extraction procedures have been designed to free thiamin before analytical methods are employed. For some more complex biological materials, further treatment or purification may be necessary to remove compounds which might interfere with the analyses.

The fluorometric thiochrome method is at present the most widely used method for measuring free thiamin. It is based on the oxidation of thiamin (**1a**) to thiochrome (**8**) by an alkaline solution of potassium ferricyanide (see Section 6.4). Mercury(II) chloride or cyanogen bromide can also be used as oxidant. The thiochrome is extracted into isobutanol and the fluorescence of the extract at an emission wavelength of 436 nm compared with that of a standard thiochrome solution.

Thiamin can also be determined spectrophotometrically by measuring its UV absorption at 266 nm, but only in cases where no other materials absorbing at this wavelength are present in significant amounts. A less sensitive and less specific method is a colorimetric test based on the formation of a diazotized aromatic amine from thiamin. Methods based on high performance liquid chromatography offer the advantages of specificity, simplicity, ease of use, and reduced time of analysis [681].

Although earlier bioassays were performed on animals, modern methods make use of microorganisms, a large variety of which have been shown to require thiamin for their growth and reproduction (see Section 6.6). The main disadvantage of using microorganisms is their relative lack of specificity, as some respond either to the thiazole moiety or to the pyrimidine precursor or to intact thiamin. Assays based on *Lactobacillus viridescens* and *Lactobacillus fermenti* are presently the most widely used, partly because both are thiamin specific.

Microbiological assays are simple, inexpensive and quite sensitive (detection limit of 5 – 50 ng thiamin), but their main drawback is the longer period of time to obtain the results.

7. Riboflavin

7.1. Introduction

According to IUPAC rules [691], riboflavin [*83-88-5*] (**1**) is the valid designation for 7,8-

dimethyl-10-(D-1′-ribityl)isoalloxazine, also known as vitamin B_2 or lactoflavin.

1

Until about 1970, this compound was generally called 6,7-dimethyl-9-(D-1′-ribityl)-isoalloxazine in the literature because of a different numbering of isoalloxazine.

Riboflavin occurs in nature as the free vitamin, as the 5′-phosphate (**2**) or flavin mononucleotide [*130-40-5*] (FMN), and as the 5′-adenosine diphosphate (**3**) or flavin adenine dinucleotide [*146-14-5*] (FAD).

2

3

7.2. History

A water-soluble growth factor present in milk was mentioned for the first time in 1913 [692]. In 1917, this heat-stable growth factor was isolated from rice bran and separated as a homogeneous fraction from another, heat-sensitive compound having vitamin character. The second compound was able to cure a certain type of polyneuritis [693]. Thus, vitamin B, which was considered to be homogeneous until then, was separated into the vitamins B_1 and B_2.

In 1932, WARBURG and CHRISTIAN described a yellow enzyme which they obtained from aqueous extracts of yeast [694]. In the following year, they separated this enzyme into a protein and a dye component and showed that neither component alone is enzymatically active [695]. The isolation of the protein-free dye in the crystalline state from chicken egg white was achieved in 1933 [696].

It was shown later that the flavins isolated from various sources, which were called ovoflavin, lactoflavin, uroflavin, hepatoflavin, vitamin B_2, and vitamin G, depending on the source, were all identical. The name riboflavin gained acceptance after 1937 when it was recognized that this vitamin is a derivative of ribose.

The structure of riboflavin was established in 1933 – 1935 by the groups of KUHN and KARRER. The key reactions were:

1) Formation of lumiflavin (**4**) on exposure to light under alkaline conditions. The identification of one of the cleavage products as a tetrahydroxybutyl group [697].
2) Alkaline degradation of lumiflavin to 4,5-dimethyl-2-(methylamino)aniline [698], which allowed the identification of lumiflavin as 7,8,10-trimethylisoalloxazine.
3) Total synthesis of riboflavin, whereby the synthesis of different stereoisomeric flavin-10 derivatives led to the establishment of the configuration of the tetrahydroxybutyl side chain of riboflavin [699–701].

7.3. Physical and Chemical Properties

Riboflavin (**1**), M_r 376.36, crystallizes as yellow, bitter-tasting needles. The melting point with decomposition is between 271 and 293 °C,

depending on the heating rate. The solubility in 100 mL water is 5 mg at 7 °C and 13 mg at 27 °C. It can be improved by the addition of, e.g., boric acid, urea, nicotinamide [702], or xanthine compounds [703]. At 27 °C, 4.5 mg of riboflavin dissolves in 100 ml of ethanol. Riboflavin is poorly soluble in pentanol, cyclohexanol, benzyl alcohol, and phenol. It is insoluble in acetone, ether, chloroform, and in aliphatic or aromatic hydrocarbons. It is freely soluble in dilute aqueous alkali solutions, but decomposes rapidly. Neutral aqueous solutions of riboflavin have an intense yellow color (λ_{max} at 445, 372, 265, and 220 nm) and exhibit a green fluorescence (maxima at 530 and 565 nm).

The specific rotation $[\alpha]_D^{25}$ is +59° ($c = 0.5$ in 37 % HCl). Light decomposes riboflavin in neutral or weakly acidic solutions to give lumichrome [*1086-80-2*].

Lumichrome

Irradiation of alkaline solutions with visible light produces lumiflavin [*1088-56-8*] (**4**).

4

In acid solution, riboflavin is resistant to oxidizing agents (e.g., H_2O_2, HNO_3, or halogens) up to ca. 100 °C. This property is used in the purification of crude products during production. Sodium dithionite ($Na_2S_2O_4$) reduces riboflavin with the uptake of two hydrogen atoms to give the colorless leucoriboflavin, which can readily be reoxidized to riboflavin by shaking with air. This reaction can be used in the analytical determination of riboflavin (see Section 7.9.).

Riboflavin binds heavy metals (e.g., Fe, Mo, Cu, Ag, Cd, Ni, Zn, Co), forming deeply colored complexes (metal chelates) [704], for example:

Flavin mononucleotide (**2**) crystallizes as the monosodium salt with two molecules of water of crystallization. Its solubility (pH 4.5) in water, 5 g/100 mL, is much higher than that of riboflavin. It is poorly soluble or insoluble in ethanol, ether, chloroform, and benzene. Owing to its high solubility in water, it is used instead of riboflavin in the production of solutions of the vitamin.

Like riboflavin, FMN is instable in alkaline solution. In an acidic medium, this phosphate ester is hydrolyzed to riboflavin. FMN is most stable at pH 6.

7.4. Occurrence

Riboflavin is one of the vitamins that occur ubiquitously. It is contained in all plant and animal cells. Certain bacteria, yeasts, fungi as well as the organs liver, heart, and kidneys are especially rich in riboflavin. Appreciable amounts are also found in egg white, meat, and milk.

The concentration of riboflavin in foods (in µg/g) is as follows [683]:

White bread	20 – 100
Rye bread	73 – 250
Cows milk	20 – 300
Cheese	330 – 565
Hen's egg	275 – 350
Pork	90 – 350
Beef	40 – 350
Pork liver	2900 – 4400
Spinach	57 – 340
Potatoes	7.5 – 200

The concentration of riboflavin in human tissues (in µg/g) [682] is:

Kidney	20.0
Liver	16.0
Heart	8.3
Adrenal gland	8.2
Stomach	5.2
Ovary	4.3
Ileum	4.2
Spleen	3.6

Brain	2.5
Mammary gland	2.4
Muscle	2.0 – 2.3
Colon	2.1
Testes	2.0
Lung	1.9
Skin	1.2
Spermaduct	1.0

In the culture media of various species of bacteria and fungi (e.g., *Ashbya gossypii*, *Eremothecium ashbyii*, *Bacillus subtilis*, *Candida flareri*), riboflavin is present in concentrations far above 10 g/L (see Section 7.6.3).

7.5. Biosynthesis [684]

Riboflavin is synthesized by many plants and microorganisms. In the animal kingdom, many herbivores which do not form this vitamin in their tissues can cover their riboflavin requirement with the help of bacteria in their digestive tract.

According to BACHER [684, 705–710], the biosynthesis of riboflavin starting with guanosine triphosphate (GTP) involves the following steps (Scheme 21): opening of the imidazole ring of GTP (**5**), catalyzed by the enzyme GTP cyclohydrolase II, produces the pyrimidine derivative (**6**). Conversion of **6** to 5-amino-6-ribitylamino-2,4(1*H*,3*H*)-pyrimidinedione (**10**) proceeds via **8** in fungi and via **7** in bacteria, respectively. The condensation of **10** with the C_4 building block L-3,4-dihydroxy-2-butanone-4-phosphate (**12**) leads to 6,7-dimethyl-8-ribityllumazine (**13**). In *Bacillus subtilis*, this step is catalyzed by the β-subunit of riboflavin synthetase. The α-subunit of riboflavin synthetase catalyzes the dismutation of the lumazine (**13**) to give riboflavin (**1**) and the pyrimidinedione (**10**).

7.6. Production

7.6.1. Syntheses

The structural elucidation of riboflavin (**1**) was completed with the first syntheses conducted by KARRER [711–713] and KUHN [714–716]. KARRER et al. reacted 2-(ethoxycarbonylamino)-4,5-dimethylaniline (**14**) with D-ribose, hydrogenated the resulting Schiff base to give the corresponding *N*-ribitylamine (**15**), and obtained *N*-(2-amino-4,5-dimethylphenyl)-D-1′-ribitylamine (**16**) after alkaline hydrolysis. Reaction with alloxan [*2244-11-3*] (**17**) in hydrochloric acid medium gave riboflavin (**1**) in 15 % yield, based on D-ribose. KUHN et al. directly hydrogenated the Schiff base formed from nitroxylidine (**18**) and D-ribose to compound **16** (Scheme 22).

An improved yield of **16** was attained by introducing the amine group at the stage of *N*-(3,4-dimethylphenyl)-D-1′-ribitylamine (**19**), which is obtainable from 3,4-dimethylaniline and D-ribose. This was achieved by coupling **19** with benzenediazonium chloride to give *N*-(2-phenylazo-4,5-dimethylphenyl)-D-1′-ribitylamine (**20**), followed by reductive cleavage of the azo double bond with sodium dithionite [717]. Cyclocondensation of **16** with alloxan (**17**) produced riboflavin (**1**) in a yield of 38 %, based on D-ribose.

Substantial progress in the synthesis of riboflavin was made by TISHLER [718] who found that in a weakly acidic medium, the azo compound (**20**) can be directly reacted with barbituric acid [*67-52-7*] (**21**) to give riboflavin (**1**), with elimination of aniline. Thus, the reduction of **20** to **16** was no longer required, and instead of the relatively expensive alloxan (**17**), the more readily available barbituric acid (**21**) was used in the synthesis. The total yield of riboflavin (**1**) was increased to 46 %, based on D-ribose.

Scheme 21. Biosynthesis of riboflavin

Subsequently, major efforts were made to replace D-ribose, which is not widely available, by other sugars. For example, ribamide (**22**), made from D-ribonolactone and 3,4-xylidine, was directly [719,720] or, after acetylation via the imide chloride (**23**), catalytically hydrogenated to give **19** [721]. D-Arabinose, which is readily available, was reacted with 3,4-xylidine to yield arabinoside (**24**). Amadori rearrangement with benzoic acid gave the keto compound (**25**), which could then be catalytically hydrogenated to **19** in alkaline solution [722,723]. As a result of moderate total yields, none of these syntheses has achieved importance in the production of flavins.

In the 1970s, a novel synthesis of flavin was described by YONEDA et al. They condensed **19** with 6-chlorouracil (**26**) to give 6-(*N*-3,4-di-

Scheme 22. Synthesis of riboflavin

methylphenyl)-*N*-D-1′-ribitylamino)uracil (**27**). Nitrosation with nitric acid and reduction of the resulting *N*-oxide (**28**) with sodium dithionite yielded riboflavin (**1**) in a total yield of ca. 70 % [724].

Riboflavin (**1**) was also obtained in good yield by autoxidation of the amine (**29**), which was made from **19** and 6-chloro-5-nitrouracil (**30**), followed by catalytic hydrogenation of the nitro compound (**31**) [725]. Nevertheless, these syntheses have not yet attained economic importance, mainly because of the multistep production of the uracils (**26**) and (**30**) from barbituric acid (**21**).

7.6.2. Industrial Chemical Production

Commercial syntheses of riboflavin require economic pathways for the production of D-ribose (**32**). Three processes, all starting with D-glucose [*492-62-6*] (**33**) should be mentioned here.

Oxidation of D-glucose with oxygen in aqueous potassium hydroxide solution [726] yields potassium arabonate (**34**) in ca. 90 % yield. **34** is converted to crystalline calcium arabonate (**35**). Heating **35** in aqueous solution to ca. 140 °C leads to an equilibrium mixture of epimeric salts, containing ca. 30 % calcium D-ribonate (**36**).

After separation of high-molecular colored side products by adsorption on activated carbon, **35** is isolated by crystallization [727], the mother liquor is acidified with sulfuric acid, and the poorly soluble calcium sulfate is separated. The D-ribonolactone [*5336-08-3*] (**37**) in the mother liquor is purified by crystallization from *n*-butanol and then reduced with sodium amalgam in aqueous solution in the presence of boric acid [728]. The sodium hydroxide solution formed is neutralized with sulfuric acid, sodium sulfate being precipitated with methanol and separated. A D-ribose solution is obtained which contains low amounts of starting material and ribitol and is directly further processed. The total yield of D-ribose (**32**) is 40 %, based on **33**.

In a more recent chemical process, D-ribose (**32**) is made from D-glucose (**33**) in three steps with a total yield of ca. 56 % [729]. **33** is fermentatively oxidized to sodium D-gluconate [*527-07-1*] (**38**), which is, in turn, oxidatively degraded to D-arabinose [*28697-53-2*] (**39**) with sodium hypochlorite. After separation of sodium chloride, **39** is crystallized from methanol by electrodialysis. Epimerization of **39** with molybdic acid in aqueous solution gives an equilibrium mixture containing ca. 25 % D-ribose (**32**), from which the starting material can be separated by crystallization and recycled [730]. The resulting D-ribose mother liquor can be used without further purification for the synthesis of riboflavin (**1**). In an advantageous process variant, molybdic acid is fixed to a basic ion exchanger and the process is conducted continuously [731].

D-Ribose (**32**) is obtained directly from D-glucose (**33**) by fermentation with microorganisms of the genus *Bacillus* which have no transketolase activity and do not form spores [732]. Especially productive are genetically engineered strains which overexpress the gluconate operon [733]. After separation of the biomass, decoloration, desalting, and evaporation of the filtrate, **32** is obtained by crystallization from water – ethanol mixture in a yield of ca. 45 %.

In the commercial synthesis of riboflavin, the three step reaction sequence, **32** → **19** → **20** → **1**, conceived by KARRER and TISHLER, is used. The total yield has been increased to >60 % by optimizing the original reaction conditions.

The readily available compound 3,4-xylidine is reacted with D-ribose (**32**) in methanol. The resulting riboside is catalytically hydrogenated to give *N*-(3,4-dimethylphenyl)-D-1′-ribamine (**19**) without isolation, and the product is purified by crystallization.

Coupling of **19** with phenyl diazonium salt in a buffered aqueous solution yields crystalline *N*-(2-phenylazo-4,5-dimethylphenyl)-D-1′-ribamine (**20**). Dry **20** is converted to riboflavin (**1**) by cyclocondensation with barbituric acid in a weakly acidic medium. Mixtures of dioxane and acetic acid or di-α-substituted carboxylic acids have proved suitable as solvents [734]. Crude **1** can be purified by reprecipitation from hydrochloric acid or dilute sodium hydroxide solution, possibly with the addition of hydrogen peroxide [735, 736].

7.6.3. Industrial Production by Fermentation

Riboflavin (**1**) can be produced microbiologically. At present, the microorganisms *Bacillus subtilis*, the ascomycetes *Eremothecium ashbyii*, *Ashbya gossypii*, and the yeasts *Candida flareri*

and *Saccharomyces cerevisiae* are used [737–740]. The nutrient media employed are molasses or plant oils as carbon source, inorganic salts, amino acids, animal or plant peptones and proteins, as well as vitamin additives. In a sterile aerobic submerged process, yields much higher than 10 g of riboflavin per liter of culture broth are obtained in a few days with good aeration and stirring at temperatures below 30 °C.

After separation of the biomass, evaporation and drying of the concentrate, an enriched product with a vitamin B_2 content of up to 80 % is obtained. The majority of the riboflavin produced by fermentation is used in animal feeds. The companies ADM (United States) and BASF (Germany) produce riboflavin microbiologically.

7.6.4. Syntheses of Flavin Mononucleotide (FMN)

Flavin mononucleotide, FMN, (**2**) was first produced by KUHN by reacting riboflavin (**1**) with phosphorus oxychloride [741]. Of the numerous phosphorylation reagents tested [742], partially hydrolyzed phosphorus oxychloride has been used most often [743]. A complex mixture of various riboflavin phosphates is always produced in this process. These can be separated by RP-HPLC and identified with the aid of authentic preparations [744].

In a commercial process employed since 1954 by Hoffmann-La Roche [745, 746], after phosphorylation, repeated crystallization is used to separate **2** as the diethanolamine salt from isomeric phosphates and unreacted **1**. Resalting with sodium acetate and crystallization from water – ethanol yields FMN (**2**) in yields of >80 %.

In a more recent process, unreacted riboflavin (**1**) is separated on polar adsorption resins made by the copolymerization of acrylic acid derivatives with divinylbenzene [747]. Subsequent fine purification can be achieved by evaporative crystallization or by chromatography on RP silica gel with water – methanol. Products purified by crystallization contain ca. 75 % FMN (**2**) and ca. 10 % 4′-FMN. Chromatographically purified preparations exhibit a ca. 90 % content of active ingredient but still contain ca. 5 % of 4′-FMN.

7.6.5. Syntheses of Flavin Adenine Dinucleotide (FAD)

The synthesis of flavine adenine dinucleotide FAD (**3**) comprises the condensation of FMN (**2**) with adenosine 5′-phosphate (AMP). The main problem is preventing formation of symmetrical phosphate esters; this is achieved by using activated AMP. The compounds morpholid [748], imidazolid [749], and products of reaction of AMP with α-pyridone [750] or with diphenylphosphoryl chloride [751] are used as activated derivatives of AMP. FAD yields of up to 70 % are attained, depending on the method employed.

FAD can also be isolated from the mycelium of cultures of *Eremothecium ashbyii* [752].

FAD can also be produced from riboflavin and AMP by fermentation with genetically engineered *E. coli* strains that overexpress the enzymes flavokinase and FAD synthetase [753, 754] (Scheme 23).

Table 26. Flavoproteins and their functions

Enzyme	Coenzyme	Function
Acyl-CoA dehydrogenase	FAD	first dehydrogenation step in the β-oxidation of fatty acids
Electron transferring flavoprotein (ETF)	FAD	transfer of hydrogen from acyl-CoA dehydrogenase to ubiquinone
Xanthine oxidase	FAD	oxidation of hypoxanthine to xanthine and xanthine to uric acid in purine degradation
Succinate dehydrogenase	FAD	dehydrogenation of succinate to fumarate in the citric acid cycle
Dihydroliponamide dehydrogenase	FAD	transfer of hydrogen from dihydroliponamide to NAD in the 2-oxo acid oxidase system
NADH cytochrome c reductase	FMN	transfer of hydrogen from NADH to ubiquinone in the respiratory chain
Monoamino oxidase	FAD	oxidation of monoamines and diamines
Aldehyde oxidase	FAD	oxidation of aldehydes to carboxylic acids
Glutathione reductase	FAD	reduction of oxidized to reduced glutathione

7.7. Importance for the Organism

In the human and animal organism, riboflavin acts as the coenzyme of a series of oxidation and reduction enzymes classified as

Scheme 23. Fermentative production of FAD

flavoproteins. More than 100 flavoproteins are known and more than 40 are found in the human organism. Examples are succinate dehydrogenase, lactate oxidase, glutathione reductase, and NADH/NADH$_2$ cytochrome c reductase (see Table 26).

Riboflavin is specifically bound to these enzymes as flavin mononucleotide (FMN) or flavin adenine dinucleotide (FAD) via the 8-methyl group of isoalloxazine.

In energy producing metabolism, flavoproteins act as intermediate hydrogen carriers in the oxidation of substrates and are reoxidized by enzymes with a higher oxidation potential (e.g., cytochrome c). In this process, the hydrogen or electron acceptor and donor are the coenzymes FAD or FMN [685, 755]. Since flavoproteins are involved in intermediary metabolism in diverse ways, riboflavin deficiency in the diet has an effect on many processes and causes deficiency symptoms.

Riboflavin is resorbed exclusively in the free form, mainly in the small intestine. After resorption, riboflavin is rephosphorylated to FMN by riboflavin kinase in the mucosa cells. FMN is then converted to FAD, primarily in the liver.

The elimination of riboflavin proceeds predominantly via the kidneys (urine).

7.8. Requirements, Deficiency Symptoms, and Therapeutic Application [686]

To prevent clinical deficiency symptoms in adults, 0.8 – 0.9 mg of riboflavin per day are generally sufficient. However, this amount cannot be considered adequate in the sense of an optimal supply.

The German Society for Nutrition (1991) recommends the following amounts: women 1.5 mg, men 1.7 mg, pregnant women 1.8 mg, nursing mothers 2.3 mg.

In humans, the most characteristic symptoms of a diet deficient in riboflavin (ariboflavinosis) are rhagades and fissures at the corners of the mouth and lips (cheilosis), atrophic glossitis, magenta colored tongue, seborrheic dermatitis in the facial area, and dystrophy of the finger nails. Of the diverse eye problems, conjunctivitis, corneal vascularization with the feeling of a foreign body and photophobia are noteworthy

[687]. Neurological symptoms such as paresthesia in the legs, a burning sensation in the feet, ataxia, and tremor have been observed. On controlled administration of only 0.5 mg of riboflavin per day, deficiency symptoms occur after 4 – 10 months [756].

Although clinical B_2 deficiency symptoms are now practically unknown in the industrial countries, the supply of this vitamin in all groups of society cannot be regarded as satisfactory. The 1991 national study on consumption and the nutritional report of 1992 show that the riboflavin intake of a large percentage of young girls and women in Germany is much less than the amounts recommended by the German Society for Nutrition.

Proven applications of vitamin B_2 are in the prophylaxis and treatment of clinical riboflavin deficiencies. These can have various causes:

1) Inadeqate and false nutrition
2) Increased requirement (e.g., during pregnancy and lactation)
3) Malabsorption
4) The result of phototherapy in newborn hyperbilirubinemia

In prophylaxis, vitamin B_2 is generally administered in daily doses of 1 – 5 mg, usually in the form of multivitamin or vitamin B complex tablets. In the treatment of an established ariboflavinosis, daily doses of up to 25 mg are administered.

In the food industry, riboflavin is used on a large scale together with other vitamins in the fortification of various foods, such as flour, baby foods, cereals, and multivitamin juices.

Riboflavin is of great importance in animal feeds, especially as an additive to poultry and pig feed. In these animals, a lack of riboflavin causes growth retardation, poor utilization of feed, and diarrhea. For laying hens, which have a greatly increased riboflavin requirement because of the high production of eggs, the addition of 5 mg per kilogram of mixed feed is recommended. The typical manifestation of riboflavin deficiency in the chicken is toes bent inwards.

7.9. Analysis [688, 689]

Microbiological, enzymatic, and physicochemical methods are used for the analytical identification of flavins. The growth tests conducted earlier with experimental animals on deficiency diets no longer play a role because they are time consuming and inaccurate.

Microbiological methods are especially suitable for the determination of low concentrations in biological media and in pharmaceutical preparations. They have the advantage of high specificity and relatively high accuracy. They are based on the effect of riboflavin on the growth of certain microorganisms, e.g., the unicellular organism *Tetrahymena pyriformis* or the lactic acid bacterium *Lactobacillus casei*. In the widely used assay with *Lactobacillus casei* [690], either the turbidity produced or the lactic acid liberated is used as the measure of the riboflavin concentration. If FMN or FAD is present, prior release of riboflavin is necessary.

The enzymatic method is based on the increase in the activity of glutathione reductase on addition of the cofactor FAD. This method provides an indication of the riboflavin status via the determination of the degree of saturation in the blood. It is a suitable method for the diagnosis of riboflavin deficiencies [757].

Physicochemical methods include the photometric measurement of the yellow color of riboflavin and the measurement of the characteristic yellow-green fluorescence. In both cases, riboflavin is determined either directly or as lumiflavin (**4**), which is formed on irradiation. Polarography is also employed for determination.

In the direct photometric method, the absorption is measured at 445 nm, the maximum exhibited by the yellow color of riboflavin. Since the specific extinction ($\varepsilon^{1\,\%}_{1\,\mathrm{cm}} = 323$) is relatively low, this method is not very sensitive. In addition, it requires the absence of other yellow substances. Therefore, this method is restricted to the measurement of high-percentage products without interfering components [688].

The fluorometric method is more sensitive. It involves the measurement of the fluorescence with a maximum at 530 nm which appears on irradiation with UV light. Its intensity is constant in the pH range 3 – 5 and depends only on the concentration of riboflavin. In some cases, interference by accompanying substances with a similar fluorescence can be eliminated by quenching the fluorescence of riboflavin with $Na_2S_2O_4$. This method is suited to the determination of ri-

boflavin in pharmaceutical preparations and in biological media [688].

In the lumiflavin method, riboflavin is converted to lumiflavin (**4**) by irradiation. This compound can be extracted by shaking with trichloromethane and measured either photometrically at 450 nm or fluorometrically at 513 nm.

The specificity and the sensitivity, especially of the fluorometric lumiflavin method, are higher than those of the direct methods. For this reason, this method is used more frequently [688].

Riboflavin can also be determined by using a straightforward polarographic method [758].

High-pressure liquid chromatography (HPLC) is the most important method for the analysis of riboflavin, FMN, and FAD. HPLC is the fastest and most sensitive method, especially for the determination of these components in complex mixtures, such as foods, and in the analysis of fermentation samples [759–761].

7.10. Economic Aspects

The present worldwide requirement of riboflavin is ca. 2400 t/a. Of this, ca. 70 % is used as feed additive, 20 % for pharmaceutical purposes, and 10 % in foods.

The world market price has remained fairly constant over the past ten years, at ca. 45 €/kg for feed quality and ca. 54 €/kg for pharmaceutical quality.

Producers of riboflavin are Hoffmann-La Roche (Switzerland), BASF (Germany), ADM (United States), and Takeda (Japan). There are also local producers in the Commonwealth of Independent States and in China.

7.11. Tolerance

Riboflavin causes no pharmacological side effects in animals or human beings and can be regarded as completely nontoxic. The administration of oral doses of up to 10 g/kg to rats and 2 g/kg to dogs produced no acute toxicity. Intraperitoneal administration to rats gave an LD_{50} value of 560 mg/kg.

8. Vitamin B_6

8.1. Introduction

Vitamin B_6 is a water-soluble vitamin. The term vitamin B_6 refers to a group of six compounds that are chemically closely related and, under physiological conditions, biochemically (enzymatically) interconvertible. These compounds (**1**) have in common the structural element 2-methyl-3-hydroxypyridine and bear two other substituents in positions 4 and 5 (Table 27).

Table 27. The vitamins B_6

R^1	R^2	Name
CH_2OH	OH	pyridoxine (**2**)
CH_2OH	OPO_3H_2	pyridoxine 5′-phosphate (**3**)
CHO	OH	pyridoxal (**4**)
CHO	OPO_3H_2	pyridoxal 5′-phosphate (**5**)
CH_2NH_2	OH	pyridoxamine (**6**)
CH_2NH_2	OPO_3H_2	pyridoxamine 5′-phosphate (**7**)

1

In 1973, the IUPAC – IUB Commission on Biological Nomenclature [762] proposed a change in the numbering of the pyridine ring. Accordingly, the common structural unit (**1**) should be called 5-hydroxy-6-methylpyridine. Until now, however, this proposal has been largely ignored in the literature (especially with regard to the 5′-phosphates which should now be named 3′-phosphates).

The commercial form of vitamin B_6 is pyridoxine hydrochloride [*58-56-0*] (**8**), which is more stable than the other compounds in this series.

8.2. History

In 1926, a syndrome similar to pellagra (pellagra is characterized by skin changes and disturbances of the nervous system, digestion, growth, fertility, blood count, etc.) was induced in rats on

a diet deficient in "vitamin B complex" [763]. This syndrome was called rat acrodynia. From 1934 to 1936, GYÖRGY et al. [764] showed that vitamins B_1 and B_2, which were both known at that time, could not cure this rat dermatitis. They showed that another vitamin, designated antidermatitis vitamin, adermin, or vitamin B_6, must be responsible for the cure. Based on GYÖRGY's exact animal model tests, the isolation (from yeast and rice bran) and structural elucidation of pyridoxine hydrochloride (**8**) were achieved simultaneously by five groups in 1938 [765].

Pyridoxine hydrochloride (**8**) was synthesized in 1939 by two teams working independently [766]. Between 1942 and 1945, SNELL et al. showed by using microbiological experiments that vitamin B_6 is not a homogeneous substance, but a group of six interconvertible compounds **2**–**7** [767].

Although **8** was isolated as early as 1932 [768], its vitamin function was not recognized at that time.

8.3. Physical Properties

A compilation of the physical properties of **2**–**8** is given in [769–772]. The properties of the commercial product pyridoxine hydrochloride (**8**), including its spectra, are described in detail in [770, 771]. All vitamin B_6 compounds are sensitive to light and, as pyridine bases, form salts with acids. They decompose when heated for longer periods in neutral or basic aqueous solutions.

Pyridoxine [*65-23-6*] (**2**), (CA: 3,4-pyridinedimethanol, 5-hydroxy-6-methyl), 2-methyl-3-hydroxy-4,5-bis(hydroxymethyl)pyridine, $C_8H_{11}NO_3$, M_r 169.18. Colorless needles (from acetone), *mp* 159 – 160 °C, soluble in water, methanol, ethanol, and acetone; thermolabile as solid and in solution.

2

Pyridoxine hydrochloride [*58-56-0*] (**8**), (CA: 3,4-pyridine-dimethanol, 5-hydroxy-6-methyl, hydrochloride), $C_8H_{12}ClNO_3$, M_r 205.64.

8

Colorless platelets or rods from ethanol – acetone, *mp* 205 – 212 °C (decomp.). Soluble in water (22 g/100 mL at room temperature), ethanol (1.1 g/100 mL), and propylene glycol. Poorly soluble in methanol and acetone, and insoluble in ether and chloroform. Aqueous solutions are stable at room temperature (120 °C for at least 30 min). The pH of a 10 % aqueous solution is 3.2.

Pyridoxine 5′-phosphate [*447-05-2*] (**3**), [CA: 3,4-pyridine-dimethanol, 5-hydroxy-6-methyl, α-3-(dihydrogen phosphate)], $C_8H_{12}NO_6P$, M_r 249.16.

3

White needles from concentrated aqueous solutions, *mp* 212 – 213 °C (decomp.), soluble in water, and insoluble in ethanol.

Pyridoxal [*66-72-8*] (**4**), (CA: 4-pyridinecarboxaldehyde, 5-hydroxy-3-(hydroxymethyl)-6-methyl), 3-hydroxy-5-hydroxymethyl-2-methyl-4-pyridinecarboxaldehyde, $C_8H_9NO_3$, M_r 167.16.

4

The aldehyde form is in equilibrium with the cyclic hemiacetal form. Readily decomposing compound, independent of pH.

Pyridoxal hydrochloride [*65-22-5*] (**9**), (CA: 4-pyridinecarboxaldehyde, 5-hydroxy-3-(hydroxymethyl)-6-methyl, hydrochloride), $C_8H_{10}ClNO_3$, M_r 203.63.

9

Almost colorless rhombic crystals, *mp* 177–181 °C (decomp.), soluble in water (50 g/100 mL) and 96 % ethanol (1.7 g/100 mL), insoluble in acetone, ether, and chloroform. In solution, **9** is less stable than **8**.

Pyridoxal 5′-phosphate [*54-47-7*] (**5**), (CA: 4-pyridinecarboxaldehyde, 5-hydroxy-6-methyl-3-[(phosphonooxy)-methyl]), $C_8H_{10}NO_6P$, M_r 247.14.

5

The monohydrate of **5** [*41468-25-1*], $C_8H_{12}NO_7P$, M_r 265.15, forms yellowish needles, *mp* 139–142 °C (decomp.), solubility in water 0.5 %, less soluble in ethanol, and insoluble in acetone and ether.

Pyridoxamine [*85-87-0*] (**6**) (CA: 3-pyridinemethanol, 4-(aminomethyl)-5-hydroxy-6-methyl), 3-hydroxy-4-aminomethyl-5-hydroxymethyl-2-methylpyridine, $C_8H_{12}N_2O_2$, M_r 168.20. Crystals, *mp* 193 °C, soluble in water and ethanol.

6

Pyridoxamine dihydrochloride [*524-36-7*] (**10**), $C_8H_{14}Cl_2N_2O_2$, M_r 241.12. Colorless hygroscopic platelets, *mp* 228 °C (decomposition), soluble in water (50 g/100 ml) and in 96 % ethanol (0.65 g/100 mL), insoluble in ether and chloroform.

10

Pyridoxamine 5′-phosphate [*529-96-4*] (**7**) [CA: 3-pyridinemethanol, 4-(aminomethyl)-5-hydroxy-6-methyl, α-(dihydrogenphosphate)], $C_8H_{13}N_2O_5P$, M_r 248.18.

7

The dihydrate of **7** [*84878-64-8*], $C_8H_{17}N_2O_7P$, M_r 284.2, forms rhombic platelets; *mp* of the hydrochloride 240 °C (decomp.).

8.4. Chemical Reactions [770, 772, 773]

Many of the reactions and syntheses in vitamin B_6 chemistry date from the years following the discovery and isolation of pyridoxine. These reactions often aided the structural elucidation and proof of structure of compounds **2** to **8**. Since the commercial form of vitamin B_6 is pyridoxine hydrochloride (**8**), some characteristic reactions of pyridoxine (**2**) are described here (see Scheme 24).

Pyridoxine (**2**) contains three reactive hydroxyl groups. The OH group in position 3 of the pyridine ring reacts with iron(III) ions to give the red or orange color typical of aromatic hydroxyl groups. This OH group can be esterified and etherified. Together with the 4-hydroxymethyl group, six-membered cyclic ketals or acetals (**10**) can be formed with ketones and aldehydes. The two hydroxymethyl groups in positions 4 and 5 undergo reactions typical of groups of this type, e.g., ester formation. Under acid catalysis, reactions with ketones and aldehydes produce, apart from **10**, seven-membered cyclic ketals or acetals (**11**). Of the two CH_2OH groups, the more reactive is the one in position 4. For example, oxidation

of **2** with MnO_2 gives pyridoxal (**4**), which can be further oxidized by O_2 under catalysis with cyanide to give pyridoxine 4-carboxylic acid (**12**) [*82-82-6*]. Although acidic aqueous solutions of **2** are quite stable even at 100 °C, it reacts with inorganic acid halides or hydrohalic acids under drastic conditions. With HCl, for instance, depending on the reaction conditions, the compounds **13** [*5196-20-3*], **14** [*102694-13-3*], and **15** [*13983-22-7*] are formed. Acetylation can give the 4′,5′-diacetate **16** [*26280-83-1*] or the 3,4′,5′-triacetate **17** [*10030-93-0*] depending on the reaction conditions. Heating **2** with aqueous ammonia produces pyridoxamine (**6**).

8.5. Occurrence

Vitamin B_6 occurs in plants mainly as pyridoxine. Grains, potatoes, green vegetables, and legumes are especially rich in vitamin B_6. A considerable part of the vitamin occurs in plants as 5′-*O*-(*β*-glucopyranosyl)pyridoxine. Animal experiments show that this glucosylated form is apparently well absorbed but appears to be not entirely bioavailable. The main forms observed in the animal kingdom are pyridoxal and pyridoxamine. Accordingly, these forms are found in animal foods, such as meat, fish, and eggs. The concentration of vitamin B_6 in some foods is given in Table 28 [774–777].

Table 28. Vitamin B_6 content of some foods [774–777]

Food	Vitamin B_6, mg/100 g	Pyridoxine *β*-glucoside %
Potatoes	0.14 – 0.39	42
Spinach	0.208 – 0.22	50
Carrots	0.17 – 0.70	51
Cabbage	0.14 – 0.27	46
Bananas	0.26 – 0.313	3
Legumes	0.381 – 0.57	42
Meat (chicken beef, pork)	0.30 – 0.70	0
Fish	0.316 – 0.45	0
Eggs	0.19 – 0.25	

8.6. Biosynthesis

Pyridoxine is synthesized in bacteria, fungi, and plants. Experiments with radioactively labelled or deuterated compounds, such as glucose and glycerol, contributed to the elucidation of the biosynthesis of vitamin B_6. Hill et al. found later that D-1-deoxyxylulose is incorporated into the pyridoxine ring and supplies the carbon atoms C 2, 2′, 3, 4, and 4′ [778,779]. According to Dempsey, 4-hydroxythreonine is a central intermediate in the biosynthesis of pyridoxine [780]. Lam and Winkler reported that 4-hydroxythreonine is made from erythrose 4-phosphate in four enzymatic steps and subsequently condensed with D-1-deoxyxylulose to give pyridoxine [781]. The enzymes that catalyze these reactions are as yet not completely known. In *E. coli*, the corresponding genes are spread over the entire chromosome and organized in complex operons. At present, biotechnological production by genetically manipulated microorganisms or the industrial isolation from natural sources is not yet of interest.

8.7. Production of Vitamin B_6 Compounds

8.7.1. Pyridoxine [770,772,782]

Pyridoxine hydrochloride (**8**) is the form of vitamin B_6 that is produced on a large scale. It is mainly used in pharmaceutical preparations and as an additive in food and feed. The other B_6 compounds, pyridoxal (**4**), pyridoxamine (**6**), and the accompanying 5′-phosphates (**3**), (**5**), and (**7**) can be made from **8**.

The five synthetic pathways known for **2** and **8** are outlined here in the order of their discovery. At first, **8** was produced entirely by the methods described in Section 8.7.1.2. Today, the methods described in Section 8.7.1.4. are exclusively employed. Intensive work on these synthetic pathways began in 1939 and 1957 and led to many patents because of the commercial interest in B_6. Since the expiry of all the basic patents on these processes, the number of new patents in this field has clearly decreased in the past years.

8.7.1.1. Oxidative Degradation of Bicyclic Heterocyclic Compounds [773]

In 1939, the teams of Kuhn [766] and Ichiba [783] published the first syntheses of **2** starting with suitably substituted isoquinoline or

Scheme 24. Reactions of pyridoxine (**2**)

quinoline derivatives [784], e.g., 4-methoxy-3-methylisoquinoline [*103988-78-9*] (**18**).

The synthesis starts with the oxidative degradation of the carbon ring to give the dicarboxylic acid (**19**) [*7442-22-0*], which is subsequently converted in several stages to **2**. The commercialization of syntheses of this type was prevented by the poor availability of the starting materials, the multiple stages involved, and the still unsolved problem of finding an inexpensive reduction of such carboxyl functions to alcohols.

8.7.1.2. Condensation Reactions with Aliphatic Precursors [770, 773, 782]

In 1939, Harris and Folkers [785] also published a synthesis of **2** which was subsequently developed into the first commercial process. The reaction of ethoxyacetylacetone [*20754-01-2*] (**20**) with cyanoacetamide [*107-91-5*] (**21**) gives the pyridone (**22**) [*17718-67-1*].

Following the same synthetic principle, the reaction of 2-amino-4-oxo-5-ethoxypent-2-ene and malodinitrile provides improved commercial

access to **22**. This method was described by Schnider as early as 1941 [786].

The conversion of **22** to **2** occurs in many stages and involves relatively heavy losses. In the following 20 – 25 years, a number of synthetic pathways for **2**, which use many different aliphatic building blocks, were described. A survey is given in [773].

8.7.1.3. From Furan Compounds

Synthesis of 3-hydroxypyridine from 2-aminomethyl-2,5-dimethoxydihydrofuran [787] was published in 1950 and used in the mid-1950s to synthesize **2** [788]. In the key step, *N*-[1-[3,4-bis[acetyloxymethyl]-2-furanyl]ethyl]acetamide [*84878-62-6*] (**23**) is converted to its 2,5-dimethoxy derivative (**24**) [*84878-63-7*] by anodic oxidation in methanol. Compound **24** is then converted to pyridoxine (**2**) by alkaline saponification and acidification.

Even after the availability of the starting compounds was improved, the cost of the starting materials, the multiple stages, and the modest total yield of the synthesis hindered its commercialization [789, 790].

8.7.1.4. Diels – Alder Syntheses with Oxazoles [770, 772]

This synthetic principle described by Kondratyeva in 1957 [791] is now used exclusively for the industrial production of pyridoxine (**2**). She found a new synthesis for pyridines via the Diels – Alder reaction of oxazoles (**25**) with maleic acid (**26**) (or derivatives). Under the reaction conditions, the Diels – Alder adduct (**27**) is aromatized to the cinchomeronic acid derivative (**28**) by the elimination of water.

An important discovery was that if good leaving groups Z are incorporated into position 5 of 4-methyloxazole (**29**), after reaction with the dienophile (**30**), the bridging oxygen atom of the bicyclic Diels – Alder adduct remains in the subsequent product and forms an OH group in position 3 of pyridine (**31**) [792].

For good results, these oxazoles should exhibit low steric hindrance and high thermal stability.

Diene Components. From the extensive patent literature, it appears that the compounds that are industrially applied are mainly 5-ethoxy-4-methyloxazole (**29**, Z = OEt) and 5-cyano-4-methyloxazole (**29**, Z = CN).

The starting material for the production of 5-ethoxy-4-methyloxazole [*5006-20-2*] (**34**) is D,L-alanine ethyl ester (**32**) [*17344-99-9*], its *N*-formyl derivative (**33**) [*4289-99-0*] being dehydrated to **34** by P_2O_5 [793].

Attempts were made to find alternatives to the formerly expensive D, L-alanine and the oxazole (**34**), which is patented. One synthesis started with inexpensive maleic anhydride (**35**) and produced D, L-aspartic acid [*617-45-8*] by NH_3 addition to the double bond. The diethyl ester of aspartic acid (**36**) [*43101-48-0*] was then used to produce 5-ethoxy-4-oxalacetic acid [*10500-75-1*] (**37**) via a known reaction sequence (*N*-formylation and dehydration) and saponification [794]. Under Diels – Alder reaction conditions, compound **37** is decarboxylated to **34**.

Another precursor of **34** is 5-ethoxy-4-methyl-oxazole-2-carboxylic acid [*23429-05-2*] (**40**), which is also decarboxylated to **34** in the Diels – Alder reaction. Here, propionic acid (**38**) is halogenated and converted to D,L-alanine with ammonia. Esterification to give **32** and reaction with ethyl oxalate gives the intermediate **39** [*23460-73-3*] which on cyclocondensation and saponification produces **40** [795].

The starting material for 4-methyl-5-cyanooxazole [*1003-52-7*] (**41**) is diketene, which is converted to ethyl acetoacetate with alcohol. Chlorination produces chloroethyl acetoacetate (**42**), which is reacted with formamide (**43**) to give 4-methyl-5-oxazolecarboxylic acid ethyl ester [*20485-39-6*] (**44**), which is dehydrated to the nitrile (**41**) via the 4-methyl-5-oxazole carboxamide (**45**) [*4866-00-6*]. This dehydration can be conducted with P_2O_5/quinoline [796], acetic anhydride [797], in a catalytic gas-phase reaction [798], or under very mild condition with cyanuric chloride [799].

Dienophiles. Derivatives of maleic acid or fumaric acid (e.g., their esters or nitriles) react as dienophiles with the oxazoles used as dienes in the Diels – Alder reaction (e.g., **34** or **41**), giving very good results. However, the above-mentioned expensive reduction steps of the resulting pyridoxine dicarboxylic acid (derivatives) have prevented industrial application.

With regard to the oxidation state, 2-butene-1,4-diol would be the ideal dienophile if the oxazole diene **34** or **41** is used. However, the first-named compound reacts very poorly. Its openchain derivatives, e.g., the ether or ester, react better but are still fairly unreactive. (Nevertheless, (*Z*)-2-butene-1,4-diol-diacetate [*25260-60-0*] appears to have been used in a production process by a Japanese company). In contrast, the cyclic seven-membered acetals and ketals of (*Z*)-2-butene-1,4-diol [*6117-80-2*] (**45**) [800] – e.g., the isopropyldioxepin (**47**) [*5417-35-6*] obtainable from isobutyraldehyde (**46**) [*78-84-2*] – have proved to be sufficiently reactive and stable in an inert-gas atmosphere. The compound *n*-propyldioxepin (**48**), derived from *n*-butyraldehyde, is also a suitable reagent.

Diels – Alder Reaction. The reaction of the oxazole (**34**) or (**41**) with the dioxepin (**47**) or (**48**) requires high temperatures (ca. 115 – 180 °C) and longer periods of time (ca. 10 – 20 h or more). The primary Diels – Alder adducts formed have three chiral carbon centers, resulting in mixtures of eight stereoisomers in the form of four diastereomeric pairs. Excess or unreacted starting material can be separated and recycled.

The use of 5-cyano-4-methyloxazole (**41**) and isopropyldioxepin (**47**) results in a Diels – Alder adduct that is not stable under the reaction conditions and decomposes with the elimination of hydrogen cyanide and aromatization to give **49** [*1622-67-9*] in > 90 % yield [800].

5-Ethoxy-4-methyloxazole (**34**) reacts with the dienophile (**47**) under somewhat milder conditions than **41**. In this case, the Diels – Alder adduct is much more stable and can be isolated (yield > 95 %). Under mildly acidic con-

ditions, aromatization occurs with the elimination of ethanol to give the bicyclic acetal (**49**) [772]. Heating **49** with hydrochloric acid results in almost quantitative conversion to isobutyraldehyde (**46**), which is separated and reused, and pyridoxine hydrochloride (**8**).

The above reactions of the oxazoles (**34**) and (**41**) with the dienophile (**47**) are "inverse" Diels – Alder reactions in which electron-deficient dienes react with an electron-rich dienophile. The variant corresponding to the "normal" Diels – Alder reaction has also been published [801]. Here, 4-methyloxazole [*693-93-6*] (**50**) reacts with 2,5-dihydro-3-(methylsulfonyl)furan [*41409-84-1*] (**51**).

In this combination, the dienophile and not the oxazole carries a good leaving group in the form of a sulfonyl group. This group makes the Diels – Alder reaction possible and is also required for the aromatization of the Diels – Alder adduct. However, this synthesis has problem steps which make industrial application doubtful.

Another Diels – Alder reaction for the synthesis of pyridoxine uses 1,2,4-triazine derivatives as dienes instead of oxazoles [802]. However, the elaborate synthesis of the triazines makes this synthetic principle appear totally uninteresting for an industrial process. Since all the basic patents for the various oxazole routes to **2** have expired and the price of D,L-alanine has fallen considerably in the past years, it appears that the combination **34**+**47** is used by Takeda and Daiichi, **41**+**47** by Roche, and **40**+**48** by at least one of the Chinese producers for the industrial production of pyridoxine hydrochloride (**8**).

8.7.1.5. Cobalt-Catalyzed [2+2+2]-Cycloaddition Reactions of Acetylenes and Acetonitrile

Independently, two groups have developed a new pathway to pyridoxine using cobalt-catalyzed [2+2+2]-cycloaddition reactions of protected α,ω-diyne ethers and acetonitrile [803].

However, the yields of **8** obtained were less than 10 %. For instance, the problem of the conversion of the $(CH_3)_3Si$ group at position 3 of pyridoxine to an aromatic OH group could not be satisfactorily solved.

8.7.2. Pyridoxine 5′-Phosphate

The OH groups in positions 3 and 4 of pyridoxine (**2**) can be protected with acetone/hydrochloric acid, forming the ketal (**52**). Phosphorylation of **52** at 60 °C with H_3PO_4 – P_2O_5, followed by gentle acid hydrolysis, yields **3** [804]. Pyridoxine 5′-phosphate (**3**) can also be obtained by the reduction of pyridoxal 5′-phosphate (**5**) with $NaBH_4$ [805].

Phosphorylation of **52** is also achieved with metaphosphoric acid $(HPO_3)_3$. The resulting mixture of oligophosphates can be hydrolyzed to **3** [806]. Compound (**3**) can also be produced by treating pyridoxamine 5′-phosphate (**7**) with HNO_2 [807].

8.7.3. Pyridoxal [808]

Oxidation of pyridoxine (**2**) with permanganate in the presence of hydroxylamine produces pyridoxal oxime (**53**), which can be converted to

pyridoxal (**4**) by treatment with nitrite and hydrochloric acid [809].

Direct oxidation of **2** to **4** can be conducted with $MnO_2 - H_2SO_4$ [806,810]. Isolation of **4** from solution can be advantageously achieved via its bisulfite addition product [811]. A total synthesis of **4** from aliphatic building blocks has been described [809].

8.7.4. Pyridoxal 5′-Phosphate

Pyridoxal 5′-phosphate (**5**) ("codecarboxylase") [772] can be made from pyridoxine 5′-phosphate (**3**) [803, a (Baddiley; Targa)] or from pyridoxamine 5′-phosphate (**7**) [803, a (Wilson)] [804,805] by oxidation with MnO_2 or with pyruvic acid in the presence of Cu, Fe, Ni, or Co salts [812]. Direct phosphorylation of pyridoxal (**4**) is described in [813]. Derivatives of pyridoxal in which the aldehyde group is protected by readily removable groups can be phosphorylated and **5** released by mild hydrolysis. The following protective groups have been used: *N*-dimethylglycylhydrazone [806,814], Schiff bases of aromatic amines [815] and alkenediamines [816], oxazolidines [817], and thiazolidines [818]. Starting with pyridoxine 5′-phosphate (**3**) or pyridoxamine 5′-phosphate (**7**), pyridoxal 5′-phosphate (**5**) was made by enzymatic oxidation with immobilized pyridoxamine 5′-phosphate oxidase [819]. Starting with pyridoxine 5′-phosphate (**3**), the synthesis of **5** using immobilized bacterial cells has been described [820].

8.7.5. Pyridoxamine [772,808]

Pyridoxamine (**6**) can be produced from pyridoxal oxime (**53**) by catalytic hydrogenation with PtO_2 in acetic acid [821], Pd/C [822], or by reduction with zinc dust [823]. Pyridoxamine (**6**) is obtained from pyridoxine (**2**) by reaction with NH_3 in CH_3OH [824]. It is also produced by the reductive amination of pyridoxal (**4**) [825]. Pyridoxamine (**6**) is also synthesized in a Diels – Alder reaction of 5-ethoxy-4-methyloxazole (**34**) with γ-hydroxycrotonitrile, followed by reduction of the nitrile group in position 4 of the pyridine ring to an aminomethyl group [826].

8.7.6. Pyridoxamine 5′-Phosphate

Pyridoxamine 5′-phosphate (**7**) is obtained from pyridoxal 5′-phosphate (**5**) by reaction with glutamic acid in an autoclave [827]. Starting with pyridoxamine (**6**), **7** is made by treatment with $POCl_3$ in aqueous solution [808]. However, better results are obtained when **6** is phosphorylated by heating with metaphosphoric acid, followed by degradation of the resulting 5′-triphosphate by mild acid hydrolysis [828] or by the action of H_3PO_4/P_2O_5 at 60 °C on **6** [807,829].

8.8. Metabolism and Importance for the Organism

The three nonphosphorylated B_6 vitamins are absorbed in the region of the upper small intestine (proximal jejunum) by a nonsaturable process (passive diffusion) [830]. They are phosphorylated in the liver by a pyridoxal kinase and ATP, bound to albumin, and released into the blood [831]. As a result of the binding to albumin, pyridoxal 5′-phosphate is protected from hydrolysis in circulation and is able to reach the tissues. The two phospho forms, pyridoxine 5′-phosphate and pyridoxamine 5′-phosphate, are converted to pyridoxal 5′-phosphate (PLP) by a FMN-dependent oxidase [832]. After dephosphorylation by a membrane-bound alkaline phosphatase, pyridoxal can enter the cell through the cell wall. Pyridoxal is irreversibly converted to 4-pyridoxic acid by an NAD-dependent dehydrogenase or an FAD-dependent aldehyde oxidase. This acid is excreted in the urine as the main metabolite of B_6 metabolism [833]. The enzymatic interconversion of the vitamins B_6 are shown in Scheme 25.

Pyridoxal 5′-phosphate acts as a coenzyme for many enzymes which, above all, regulate amino acid metabolism. The coenzyme is bound to an ε-amino group of a lysine residue of

Scheme 25. Metabolic interconversion of the vitamins B_6

the apoenzyme through its formyl group. Thus, the active enzyme complex is formed via the resulting Schiff base. In this way, reactions such as transamination, nonoxidative deamination, decarboxylation, and hydrodesulfurization are catalyzed. The majority of pyridoxal 5′-phosphate (75 – 80 %) is found in glycogen phosphorylases, which are involved in gluconeogenesis in plants and animals. However, the reaction mechanism is still unknown. Furthermore, pyridoxal 5′-phosphate acts in microbial racemases which catalyze the conversion of L-amino acids to D-amino acids. In addition, it appears to have a regulatory effect on steroid hormone receptors. Under physiological conditions, pyridoxal 5′-phosphate binds reversibly to steroid receptors and can modulate or inhibit the interaction between the steroid receptor complex and the specific DNA sequence [834, 835]. The physiological importance of the interaction between PLP and steroid receptors is not yet understood.

8.9. Deficiency Symptoms and Applications

A food-related vitamin B_6 deficiency manifesting itself in clinical symptoms is largely unknown in humans. Since vitamin B_6 plays an essential role in numerous biochemical processes, a lack of this vitamin is easily detectable from the resulting metabolic disturbances. Deficiencies are produced by an unbalanced diet, interference with medicines, excessive loss due to functional kidney disorders, intestinal diseases (diarrhoea, disturbances of absorption), hereditary disorders (cystathioninuria, homocysteinuria), or neurological diseases.

Patients with liver cirrhosis (e.g., alcoholics) often have a low vitamin B_6 level in the blood [836, 837]. In 15 – 20 % of women, estrogen-containing contraceptives cause an impairment of tryptophan metabolism which can be normalized by 2 – 25 mg of vitamin B_6 per day [838]. In the treatment of tuberculosis with isoniazid, side effects appear (neuritis, convulsions) which can be prevented by 25 – 50 mg of vitamin B_6 per day [839, 840]. Treatment of the rare Wilson's

disease with D-penicillamine causes impaired tryptophan metabolism which responds well to 100 mg of vitamin B_6 per day [841]. The very low plasma values found in patients with kidney diseases (chronic kidney failure, hemodialysis) or after kidney transplantation can be normalized by administration of 5 – 50 mg of vitamin B_6 per day. Some genetic diseases result in B_6 malfunctions. Included in this category are cases of infantile convulsions caused by the poor binding of vitamin B_6 to the apoenzyme glutamate decarboxylase; primary cystathioninuria, which is marked by a greatly reduced affinity of the enzyme cystathionase for vitamin B_6; or homocysteinuria, which is caused by low amounts of cystathionine β-synthase. In general, intake of 5 – 50 mg of vitamin B_6 per day results in improvements. High doses or megadoses of vitamin B_6 are often applied in the treatment of rheumatic diseases, carpal tunnel syndrome, autism, schizophrenia, learning difficulties, and mental retardation [842, 843].

8.10. Analysis

Numerous methods have been developed for the determination of vitamin B_6. Preparations enriched with pyridoxine can be determined by using UV spectra or color reactions (e.g., the reaction between pyridoxine and diethyl-*p*-phenyldiamine). The analysis of vitamin B_6 in foods, animal organs, and body fluids is complicated. Reasons for this are the different chemical forms (pyridoxine, pyridoxal, pyridoxamine, and their phosphate esters), sensitivity to heat and light, and the covalent binding of these forms to proteins. Microbiological methods are often used for the determination of vitamin B_6. The yeast strain *Saccharomyces uvarum* is generally used for this purpose [844, 845]. Frequently, all the vitamin B_6 forms can be determined by using combinations with other microorganisms, e.g., *Lactobacillus casei*, *Streptococcus faecium*. The detection limit is 0.5 – 1.0 ng. However, these methods are very time consuming. The microorganisms can mutate or suffer growth inhibition under the influence of the extracts. Pyridoxal 5′-phosphate is enzymatically determined in the blood, serum, or in erythrocytes by the decarboxylation of amino acids [846, 847]. Pyridoxal 5′-phosphate can be indirectly determined in erythrocytes by measuring the enzyme activities of erythrocyte glutamate oxaloacetate transaminase (EGOT) and erythrocyte glutamate pyruvate transaminase (EGPT) [847–849]. Gas chromatography and HPLC have also been successfully used [850, 851].

8.11. Economic Aspects

World production of pyridoxine hydrochloride (**8**) is estimated at 2550 t/a for 1993. The main producers are Roche (Germany), Takeda (Japan), and Daiichi (Japan). In the past years, the production capacity in several plants has been drastically increased, especially in China, and the estimated world capacity of $>$ 4100 t/a for 1993 greatly exceeds demand. From 1992, the market has been increasingly supplied by Chinese companies (especially by New Asiatic, Shanghai). The list price for pyridoxine hydrochloride given in [852] is \$ 50/kg. However, the actual retail prices on the world market fluctuate and are considerably lower than the list price (as of October 1994).

The historically highest retail price for **8** was 7600 \$/kg in the year of its introduction and the lowest price was \$ 30/kg in 1967.

Trade names of vitamin B_6 and its producers are, e.g., Benadon (Roche), Hexobion (Merck), Beelith (Beach Pharmaceuticals, USA), Vitamin B_6 Richard (Lab. M. Richard, France), Vitamin B_6 Streuli (Streuli, Switzerland), B_6-Vicotrat (Heyl, Germany), Pyragamma (Wörwag, Germany), and Vitamin B_6 Jenapharm (Jenapharm, Germany). All these products contain pyridoxine hydrochloride as the active agent in doses of 20 to 300 mg, and in one case 600 mg.

8.12. Requirements and Tolerance

The requirement for vitamin B_6 is influenced by various factors, especially by the daily intake of protein. The requirement increases with increasing protein absorption. In the United States, the average daily intake of vitamin B_6 in 1985 was 1.87 mg for men, 1.16 mg for women, and 1.22 mg for children of 1 – 5 years [853]. Various methods are used to estimate the requirement, e.g., direct determination of the different

forms in the blood and/or urine (excretion of 4-pyridoxic acid), various load assays (e.g., determination of the tryptophan metabolites xanthurenic and kynurenic acid in the urine after oral tryptophan loading with 2 – 5 g), or the measurement of vitamin B_6 dependent enzymes (indirect functional determination). Since 1989, the recommended daily allowance (RDA) for vitamin B_6 in the United States has been set at 2.0 mg for men, 1.6 mg for women, 2.1 mg for pregnant and nursing women, 1.0 mg for children of age 1 – 3, 1.1 mg for 4 – 6 year old children, and 1.4 mg for children at the age of 7 – 10 [777, 853].

Pyridoxine and related compounds having vitamin B_6 activity show only low acute toxicity [854, 855]. Teratogenic and carcinogenic effects of high pyridoxine doses are unknown [856, 857]. After ingestion of excessively high doses (2 – 6 g of pyridoxine per day) over longer periods of time, peripheral neurological disorders have been observed in humans [858]. A daily intake of up to 250 mg of pyridoxine over longer periods is harmless [859, 860]. The limit at which toxic effects can appear is ca. 500 mg/d or more [861].

9. Vitamin B_{12} (Cobalamins)

9.1. Introduction

Vitamin B_{12} [*68-19-9*] belongs to the group of cobalamins, which also includes adenosylcobalamin [*13870-90-1*], methylcobalamin [*13422-55-4*] and hydroxocobalamin [*13422-51-0*]. The cobalamins and other compounds similar to B_{12} are corrinoids (Fig. 12). The corrinoids have a tetrapyrrole ring system which, compared to the porphyrins, lacks the methine bridge between rings A and D; central atom is cobalt.

The cobalt atom is coordinated by two ligands perpendicular to the plane of the tetrapyrrole ring. One of these ligands is a nucleotide linked to a propionyl group of the tetrapyrrole ring by an aminopropanol group.

All corrinoids that contain 5,6-dimethylbenzimidazole [*582-60-5*] as the nucleotide ligand are known as cobalamins. Depending on the anionic ligand, a distinction is made between vitamin B_{12} (cyanide as ligand), coenzyme B_{12} (deoxyadenosyl group as ligand), etc. The cobalamins are presented in Figure 13.

Deoxyadenosylcobalamin and methylcobalamin are physiologically active as coenzymes. Another compound found in the bodies of mammals is hydroxocobalamin, a precursor of the coenzymes. Cyanocobalamin is a form made from the naturally occurring cobalamins. It is reconverted to the coenzyme forms in the body.

Other B_{12} derivatives are found in bacteria. They have in common that the ribazole group (5,6-dimethylbenzimidaole) is replaced by imidazoles or purines. Important representatives are pseudovitamin B_{12} (Co α-[α-(5,6-dimethylbenzimidazoyl)]cobamide) of methanogenic bacteria. In addition, other corrinoids are found in acetogenic bacteria, clostridia, and sulfate-reducing and sulfur-metabolizing bacteria [862].

In 1925, Whipple and Robscheit-Robbins postulated for the first time that vitamin B_{12} is an animal protein factor. In 1926, Minot and Murphy showed that raw liver cured pernicious anemia. Subsequent work showed that this disease is caused by vitamin B_{12} deficiency. In 1948, vitamin B_{12} was isolated from liver samples by Rickes and Smith. The structure was elucidated by Hodgkin et al. in 1955. In 1972, the total chemical synthesis, with more than 70 synthetic steps, was achieved by Woodward and Eschenmoser.

Neither animals nor plants can synthesize vitamin B_{12}. According to present knowledge, the biosynthesis of corrins is restricted to microorganisms.

In humans, vitamin B_{12} is absorbed in two ways: by diffusion at higher vitamin B_{12} concentrations, and via the intrinsic factor, a mucoproteid that is formed in the mucous membrane of the stomach and specifically binds cobalamins. [The name "intrinsic factor" comes from the fact that two factors can be responsible for vitamin B_{12} deficiency: lack of B_{12} (extrinsic factor) and lack of binding protein (intrinsic factor).] The mucoprotein complex reaches the ileum, where resorption is mediated by a transport system. Even without intrinsic factor, vitamin B_{12} can be absorbed by diffusion throughout the small intestine. However, the doses needed to cover the daily requirement in this way are 10 to 100 times larger than the amounts available in foods. In the liver, vitamin B_{12} is converted to coenzyme B_{12}

Figure 12. Classification of corrinoids

Figure 13. Structure of cobalamins
R = CN^- : cyanocobalamin = vitamin B_{12}R = 5′-desoxyadenosyl group: adenosylcobalamin = coenzyme B_{12}R = methyl group: methylcobalamin = mecobalaminR = hydroxyl group: hydroxocobalamin = aquocobalamin = vitamin $B_{12\,a}$

in a reaction dependent on adenosyl triphosphate (ATP) and flavin adenine dinucleotide (FAD), and stored. Vitamin B_{12} is excreted with the bile.

With a balanced diet, humans ingest 10–30 µg of vitamin B_{12} or other cobalamins per day, of which ca. 5 µg is resorbed. This amount has also been stipulated by the German Society for nutrition and by the U.S. Food and Nutrition Board as the daily requirement for humans.

Cobalamins are predominantly ingested with animal products. In experiments with pigs, feeding exclusively with plant proteins led to stoppage of growth due to B_{12} deficiency.

In the large intestine of humans, the intestinal flora produce ca. 50 µg of cobalamins per day, which are, however, not resorbed.

In humans vitamin B_{12} deficiency causes pernicious anemia, which is characterized by a large reduction in the erythrocyte count due to a disturbance in the maturation of red blood cells. The anemia is accompanied by neurological symptoms. In most cases, pernicious anemia is due

to a lack of intrinsic factor, resulting in reduced B_{12} absorption.

In the treatment of pernicious anemia, vitamin B_{12}, hydroxocobalamin, or adenosylcobalamin is administered in a dosage of ca. 100 µg. In the case of cyanide poisoning, high doses of hydroxocobalamin are given to bind the cyanide.

Vitamin B_{12} is used as a component of diet foods, children's foods, vitamin mixtures, cereals, beverages, vitamin preparations, and as a feed additive [863].

In pig breeding, vitamin B_{12} is used in a concentration of 10 – 30 mg/t of feed. The German Feed Law permits the addition of 10 – 20 µg of vitamin B_{12} per kilogram of feed for young pigs, hens, turkeys, and ducks. Ruminants cover their requirements via the formation of B_{12} by rumen bateria.

9.2. Properties of Vitamin B_{12}

Cyanocobalamin forms dark red, odorless, tasteless crystals (needles and prisms). The crystals are hygroscopic and can absorb up to 12 % of moisture. All the corrinoids are soluble in water (ca. 1 %), poorly soluble in lower alcohols and phenols, and insoluble in acetone, chloroform, ether, and other organic solvents. Aqueous solutions are optically active. The following optical rotations are measured in dilute aqueous solutions of cyanocobalamin: $[\alpha]^{20}_{656}$: $-59 \pm 9°$, $[\alpha]^{20}_{644}$: $-110 \pm 10°$.

Aqueous solutions of cyanocobalamin are stable. Decomposition occurs only at temperatures above 120 °C at pH values below 3 or above 8. Solutions of adenosyl-, methyl-, and hydroxocobalamin are, however, sensitive to light. The decomposition temperature and solubility of some B_{12} derivatives (solids) are listed in Table 29.

Table 29. Decomposition temperature and solubility of some important derivatives of vitamin B_{12} [864]

Name	Decomposition temperatures, °C	Solubility in water, g/L
Vitamin B_{12}	210	14.1
Adenosylcobalamin	150	15.0
Methylcobalamin	210	13.4
Hydroxocobalamin	200	107.0

According to IUPAC – IUB nomenclature, the Co complexes are designated as Co α-agylkonyl-(Co β-ligandyl) cobamides. The meaning of α and β is the same as in the steroid series. Thus, cyanocobalamin is [(Co α-(5,6-dimethylbenzimidazoyl)]-Co β-cyano-cobamide, abbreviated:

Apart from cyanide, other ions can complex cobalt, in the following order of stability: $CN^- \gg SO_3^{2-} > OH^- \gg$ halides.

In alkaline solution, the cobalamins can be reduced by thiols, giving reduced vitamin B_{12r}, a Co(II) cobalamin. Further reduction gives rise to Co(I) cobalamin (vitamin B_{12s}).

Vitamin B_{12s} can be converted by methyl iodide to methylcobalamin with the formation of an organometallic bond:

Reaction with 5′-tosyl-2′3′-isopropylidene adenosine gives adenosylcobalamin.

Most of the known biochemical reactions involving adenosyl- or methylcobalamin have been found to occur in microorganisms. These include ribonucleotide reductase (DNA synthesis), propanediol dehydratase (isopropanol degradation), glutamate mutase (glutamate degradation), ethanolamine ammonium lyase (ethanolamine degradation), lysine mutase (lysine degradation), ornithine mutase (ornithine degradation), and glycerol dehydratase (glycerol degradation). In human metabolism, methyl-cobalamin is required by the enzyme methionine synthase (E.C. 2.1.1.13), and adenosylcobalamin is required by methylmalonyl CoA mutase (E.C. 5.4.9.9.2). It is probable that leucine mutase (E.C. 5.4.3.7) is also dependent on adenosylcobalamin.

9.3. Analysis

A large number of methods for the detection of vitamin B_{12} have been described [865]:

1) Microbiological growth tests (detection limit of 10^{-11} mol/L $\approx$ 10 ng/L) with *Lactobacillus leichmanii* [American Type Culture Collection (ATCC) 4797 and 7830], which reacts very specifically to cobalamin. Growth tests with *Escherichia coli* (ATCC 9637) are also possible. These are either turbidimetric assays in test tubes or growth tests on agar plates. The plate tests are mainly used in screening for a quick assessment of the productivity of mutants.
2) Chromatographic processes (detection limit of 10^{-6} mol/L $\approx$ 1 mg/L) with HPLC methods (XAD-2 columns or reversed phase RP-18 columns and photometric detection).
3) Radioimmunological methods (RIA); commercial test sets are available for serial assays.
4) UV – VIS spectroscopic methods (detection limit of 10^{-5} mol/L $\approx$ 10 mg/L). This method is only suitable for pure substances.

Aqueous solutions of cyanocobalamin have absorption maxima at (Fig. 14): $\lambda = 278$ nm ($\pm$ 1 nm), $\varepsilon^{1\,\%}_{1\,\mathrm{cm}} = 93$; $\lambda = 360$ nm ($\pm$ 1 nm), $\varepsilon^{1\,\%}_{1\,\mathrm{cm}} = 168$; $\lambda = 550$ nm ($\pm$ 1 nm), $\varepsilon^{1\,\%}_{1\,\mathrm{cm}} = 52$.

Figure 14. UV-VIS spectrum of cyanocobalamin

The absorption maxima of the other corrinoids are similar to those of cyanocobalamin.

Owing to the very low concentrations of vitamin B_{12} in foods and feeds, its detection by spectroscopic methods is possible only after purification or isolation. Microbiological methods allow very specific B_{12} detection without pretreatment of the samples. These tests are, however, less accurate and require a microbiological laboratory.

Before analysis, each of the corrinoids in corrinoid mixtures must be isolated and determined separately. If the total amount of corrinoids is sufficient, the corrinoids are converted to the cyano form and determined as vitamin B_{12}. If coenzyme B_{12} or methylcobalamin is isolated, it is necessary to work under red light because these B_{12} variants are sensitive to light.

9.4. Biosynthesis

The biosynthesis of vitamin B_{12} is one of the most complex metabolic pathways known. Many of the steps have been studied [866–868]. The metabolism has, however, not yet been fully elucidated, and various groups are working on the biochemistry and genetics of B_{12} biosynthesis. The synthesis of B_{12} in the bacteria *Escherichia coli*, *Propionibacterium shermanii, Pseudomonas denitrificans*, and *Salmonella typhimurium* has been thoroughly studied.

As in the case of hemes and chlorophylls, the precursor of the corrinoids is uroporphyrinogen III [*1976-85-8*] (uro'gen III). Uro'gen III is converted to precorrin 8$\times$ by a series of methylation

steps and elimination of the methine bridge between rings A and D.

Cobalt insertion gives rise to cobyrinic acid, insertion of a molecule of threonine [*72-19-5*] produces cobinamide [*14709-02-5*], and linkage of the "nucleotide loop" with 5,6-dimethylbenzimidazole from riboflavin (vitamin B_2) [*83-88-5*] and adenylation yields coenzyme B_{12}.

The biosynthesis of vitamin B_{12} is controlled by ca. 30 genes. In the bacterium *Salmonella typhimurium*, most of these genes are organized in a functional unit, the cob operon. The genes of *Pseudomonas denitrificans* are similarly organized.

9.5. Production

Vitamin B_{12} is produced exclusively by fermentation. With more than 70 steps, chemical synthesis is not economical.

In the past, vitamin B_{12} was isolated from fermentation residues obtained from the production of antibiotics, e.g., from streptomycin production with *Streptomyces griseus*, from neomycin fermentation with *Streptomyces fradiae*, or from chlorotetracycline production with *Streptomyces aureofaciens* [869]. In comparison with fermentation processes, however, this process is no longer economical.

Clarification sludge from anaerobic wastewater treatment is rich in vitamin B_{12} and pseudovitamin B_{12}, but extraction is not profitable.

Although more than 100 processes for the fermentative production of vitamin B_{12} are described in the literature and in patents, only five to ten are used in practice worldwide.

The most important processes are fermentation with *Pseudomonas denitrificans* and with bacteria of the genus *Propionibacterium*. Fermentations with other species have also been described [870].

Bacteria which produce B_{12} or B_{12} derivatives are listed in the following:

Propionibacteria	*Propionibacterium shermanii*
	Propionibacterium freudenreichii
Pseudomonada	*Pseudomonas denitrificans*
	Pseudomonas methanolignica
	Pseudomonas aeroginosa
Methanogenic bacteria	*Methanosarcina barkeri*
	Methanobacterium thermo-autotrophicum
Acetogenic bacteria	*Acetobacterium woodii*
	Acetobacterium spec.
Other species	*Arthrobacter hyalinus*
	Micromonaspora purpurea
	Streptomyces olivaceus
	Bacillus megaterium
	Nocardia methanophilus
	Nocardia gardeneri
	Klebsiella spec.
	Eubacterium spec.
	Rhodopseudomonas spec.
	Butyribacterium metholo-trophicum

All fermentations produce a mixture of methyl-, hydroxo-, and adenosylcobalamin. The methanogenic bacteria produce pseudovitamin B_{12} or Factor III. Isolation of the individual corrinoids is tedious. For this reason, work-up is usually carried out after the corrinoids have been converted to the cyano form by addition of cyanide.

9.5.1. Fermentation

Vitamin B_{12} is produced in fermenters which are filled with a production medium in which the bacteria grow and produce. The production medium is suited to the needs of the strains used. The fermenter is inoculated from a preculture which, in turn, comes from a working cell bank [871].

The bacterial strains used to produce vitamin B_{12} are improved in a strain-development pro-

gram. In this way, the productivity (amount of B_{12} per liter of fermentation medium per unit time) of the strains can be greatly improved. SPELLA et al. [872] have described in a program which was used to improve the productivity of *Pseudomonas denitrificans* in eight steps from 4 mg/L of B_{12} to 150 mg/L of B_{12}. In this program, the strains were treated with an agent that causes mutations (e.g., UV radiation or nitrosomethylurea [*684-93-5*]). Among the mutants, strains with improved characteristics were selected (mutation – selection process). Improved characteristics can include not only higher productivity, but also improved growth rate, improved nutrient utilization, higher tolerance to end products (e.g., propionic acid) and starting materials (e.g., dimethylbenzimidazole), or improved genetic stability. The search for improved mutants is very tedious (1 improved strain per $10^5 - 10^6$ strains).

The number of hits can be increased if it is possible to specifically search for characteristics which are connected with improved production. For instance, it is known that porphyrin synthesis reduces B_{12} production because both compounds have a common precursor in their biosynthesis. Mutants with reduced porphyrin synthesis can be recognized, e.g., by their reduced catalase activity. In the screening process, strains with reduced catalase activity are searched for first. These strains are then tested for B_{12} productivity.

It is also possible to search for improved strains by using antimetabolites (e.g., ethionine) which permit the selection of strains with altered enzyme activities.

Propionibacterium Process. The propionibacterium process is the oldest described fermentation process. *Propionibacterium shermanii* (ATCC 6707) and *Propionibacterium freudenreichii* (ATCC 13 673) are the preferred species. The carbon and energy sources are carbohydrates that are fermented to propionic acid without oxygen. The acid produced (ca. 10 % of the fermentation volume) must be neutralized (pH 7) during fermentation. An example of a production medium follows:

Glucose	120 g
Corn steep liquor	80 mL
Glycine	5 g
NH_4NO_3	3 g
$MgSO_4 \cdot 5\,H_2O$	0.5 g
Na_2MoO_4	10 µg
Calcium pantothenate	5 mg
$CoCl_2 \cdot 6\,H_2O$	10 mg
Dimethylbenzimidazole	20 g
Tap water	1 L

Propionibacteria are anaerobic organisms which grow and produce B_{12} very poorly in the presence of oxygen. However, the synthesis of 5,6-dimethylbenzimidazole, a component of B_{12}, is dependent on oxygen. Furthermore, the biosynthesis of B_{12} is inhibited by the presence of B_{12} (feedback inhibition). These problems are avoided by using a two-stage process. In an anaerobic fermentation that takes ca. 3 d, the bacteria grow and produce the vitamin B_{12} precursor cobamide (B_{12} without dimethylbenzimidazole). Subsequently, the culture is moderately aerated for 1 – 3 d to promote the biosynthesis of dimethylbenzimidazole and to complete the formation of B_{12}. As a rule, dimethylbenzimidazole is added in the second stage of fermentation, increasing the yields and reducing the fermentation time. In this way, B_{12} yields of > 150 mg/L can be achieved.

Pseudomonas Process. MILLER and ROSENBLUM [873] have isolated mutants of *Pseudomonas denitrificans* characterized by good productivities. Taxonomically, *P. denitrificans* no longer exists, having been assigned to the species *Pseudonomas* fluorescence and *Alcaligenes xylosoxidans* [874].

Pseudomonas denitrificans converts glucose to carbon dioxide, consuming oxygen in the process. In contrast to the Propionibacterium process, growth occurs with parallel synthesis of B_{12}. The fermentation is aerated and conducted at ca. pH 7 and 30 °C. After a fermentation period of 1 – 2 d, a yield of > 150 mg/L is achieved. The culture is well aerated during the logarithmic growth phase. However, the oxygen concentrations in the medium must not be high because otherwise a decrease in growth and production occurs. Dimethylbenzimidazole as B_{12} precursor is added to the fermentation medium. The growth of *Pseudomonas denitrificans* is improved by glutamate, and the synthesis of B_{12} is stimulated by betaine, choline, dimethylbenzimidazole, and cobalt. Sugar beet molasses is often used in industrial fermentations because of

its high betaine content. An example of a B_{12} production medium is present in the following:

Sugar beet molasses	105 g
Sucrose	15 g
Betaine	3 g
Ammonium sulfate	2.5 g
Magnesium sulfate	0.2 g
Zinc sulfate	0.08 g
5,6-Dimethylbenzimidazole	0.025 g
Tap water	1 L

9.5.2. Work-Up

Vitamin B_{12} and its derivatives are present inside the cell. Vitamin B_{12} is either isolated and purified or the dried cell mass is used as a concentrate in animal feeds (Fig. 15).

Figure 15. Work-up of vitamin B_{12}

Hydroxocobalamin is obtained if the natural cobalamins are converted to the chloro, sulfate, or nitrate form during extraction and then subjected to alkaline ion exchange [e.g., on Amberlite IRA 400 (OH^-)] [875]. Adenosyl- and methylcobalamin are isolated directly from the fermentation broth.

To produce a concentrate, the cells are separated from the medium with separators or centrifuges, and the cell mass is dried. Alternatively, the entire contents of the fermenter can be evaporated or concentrated and spray dried. The concentrates produced in this manner contain ca. 1 g of corrinoids per kilogram of dry matter.

For use in the feed industry, the centrifuged cell mass is heated as an aqueous suspension to lyse the cells. Depending on the production organism, other processes can also be used for lysis. The dissolved corrinoids are converted to cyanocobalamin by the addition of KCN, usually in the presence of sodium nitrite and heat. The vitamin B_{12} solution is then clarified by filtra-tion, treatment with zinc hydroxide, or similar processes. Precipitation of this aqueous solution produces a product of ca. 80 % purity which is a suitable animal feed additive. The precipitation can be performed by concentration and addition of auxiliaries such as tannic acid or cresol.

For further purification to give B_{12} of food and pharmaceutical quality, the clarified vitamin B_{12} solution can be extracted with organic solvents (cresol, carbon tetrachloride), and then with water after the addition of butanol, and again with organic solvents. Adsorption processes, e.g., with ion exchangers, aluminum oxide, or activated carbon, can be used alternatively or in addition. Pure vitamin B_{12} is obtained by crystallization after the addition of organic solvents. A detailed description is given in [871].

9.5.3. Patents and Scientific Survey

More than 1000 patents and articles on the fermentative production of vitamin B_{12} have been published.

A general protection by patent for the Propionibacterium and Pseudomonas processes no longer exists. However, a number of special process and preparation variants have been patented. Furthermore, other production organisms and substrates have been decribed. A survey is presented in Table 30.

Table 30. Survey of the patent and literature on the fermentative production of vitamin B_{12}

Company/year	Organism	Productivity	Remarks
Asahi Chemical (J) 1988			fermentation with cell recycling
Daicel Chemicals (J) 1987 – 91	*Acetobacterium, Methanosarcina*	4.1 mg/L in 124 h, 23 mg B_{12}/g DM∗	fermentation with methanol mutants
Dainippon (J) 1978 – 79	*Pseudonocardia, Nocardia*	1.85 mg/L	fermentation with methanol
Gedeon Richter (HUN) bis dato	*Propionibacterium shermanii*	26 mg/L in 10 d	different fermentation and preparation patents
Kobe Steel (J) 1992	*Methanobacterium thermoautotrophilum*		fermentation with methane
Kureha Chemicals (J) 1983	*Protami-nobacterium+ Rhodospirillum*		cell fusion
Kyowa Hakko (J) 1975	*Klebsiella*		methanol medium
Mitsubishi Gas Chemicals (J) 1987	*Eubacterium/Butyribacterium*	37 – 39 mg/L in 40 h	methanol medium, partly mixed culture
Nippon Oil (J) 1976 – 1995	*Arthrobacter, Propionibacterium shermanii*	43 mg/L in 7 d	fermentation with glucose, isopropanol, patents on work-up
Nippon Point (J) 1988			isolation of B_{12}
Nippon Zeon (J) 1980	*Candida tropicalis*	0.2 mg/L in 80 h	ethanol medium
Rhône-Poulenc, Rhône-Poulenc Rohrer (F) 1979 – 1985	*Pseudomonas denitrificans*		studies on metabolic elucidation, patents on cloning of metabolic pathways of pseudomonas
Shimizu Construction (J) 1990 – 1993	*Methanogenic*	1.4 mg/L in 4 d	
Shiseido (J) 1979 – 1987			reinfarction of B_{12}

∗ DM = dry matter.

9.6. Specifications and Legal Aspects

A USP cyanocobalamin reference standard is available (USP 207) with the following UV – VIS spectroscopic properties: maxima at 278 ± 1 nm, 361 ± 1 nm, and 550 ± 2 nm. The quotient of the absorptions at 361 and 278 nm must be 1.70 – 1.90.

The toxicity of vitamin B_{12} is extremely low. In animal experiments, vitamin B_{12} in doses of up to 1 g/kg of body weight showed no toxic effects. In humans, allergic reactions have been observed in a few cases. A connection between methylcobalamin and tumor development has also been reported. However, these effects are still disputed [876]. There is no limitation to the dosage of B_{12}; excess B_{12} is excreted.

9.7. Economic Aspects

With reference to the pure substance, the total sales of vitamin B_{12} amount to more than 10 t/a and the market volume is ca. € 77×10^6. The feed sector accounts for ca. 55 % of the sales, and the food/pharmaceutical sector for ca. 45 %. Apart from cyanocobalamin, hydroxo- and adenosylcobalamin are traded, especially on the pharmaceutical market.

North America and Western Europe represent the largest market potentials. The Asian countries including Japan are gaining importance. The remaining market volume is almost equally distributed among Brazil, the other countries in Latin America, and Eastern Europe. The African and Western Asian markets are of less importance.

More than 80 % of the total annual production of vitamin B_{12} comes from France. The company Rhône-Poulenc occupies a dominant position in both feed and pharmaceutical sectors. Roussel Uclaf, another French manufacturer, is active exclusively in the pharmaceutical sector.

Other producers are: Gedeon Richter, Hungary, with an estimated share of the market of ca. 10 %; Nippon Petrochemicals, Japan; Merind, India; and smaller producers in Eastern Europe.

10. Vitamin C (l-Ascorbic Acid)

10.1. Introduction

Ascorbic acid [*50-81-7*] (**1**) (or L-ascorbic acid, L-*xylo*-ascorbic acid, L-*threo*-hex-2-enoic acid γ-lactone) is the official IUPAC designation for vitamin C [893]. Ascorbic acid is the naturally occurring antiscorbutic vitamin. Vitamin C defi-

ciency causes scurvy, one of the oldest diseases known to humankind.

In 1928 vitamin C was isolated for the first time by SZENT-GYÖRGYI [894] and five years later its chemical structure was determined by HAWORTH and HIRST [895]. At the same time industrial production of ascorbic acid was developed, and has since reached a volume of ca. 60 000 t/a. The most significant characteristic of L-ascorbic acid is its oxidation to dehydro-L-ascorbic acid [*490-83-5*] (**2**), with which it forms a reversible redox system. This reducing property, together with its nutritional qualities and low toxicity, is the main reason for the numerous applications of vitamin C in the food and pharmaceutical industries.

Of the other three diastereomers of ascorbic acid only D-*arabo*-ascorbic acid [*89-65-6*] (**3**) (isoascorbic acid, erythorbic acid, D-*erythro*-hex-2-enoic acid γ-lactone) shows antiscorbutic activity (ca. 5 % of that of vitamin C). In some countries it is used as an antioxidant in the food industry, as a cheaper substitute for ascorbic acid.

10.2. History [882]

Although a disease remarkably similar to scurvy was known by the ancient Egyptians, it was not until 1753 that JAMES LIND described the prevention of scurvy by dietary means. He revealed scurvy to be a dietary deficiency arising from a lack of fresh fruits or vegetables. Nevertheless, scurvy incidents still occurred in times when fruits and vegetables were unavailable.

A breakthrough in scurvy research was the discovery by HOLST and FRÖLICH [896] in 1907 that guinea pigs are susceptible to scurvy. Thus, they had an animal to test various diets for their antiscorbutic activity, and they conclusively confirmed that scurvy was produced by a defective diet.

In 1928 SZENT-GYÖRGYI accomplished the isolation of pure vitamin C from the adrenal cortex of cattle, orange juice, cabbage water, and later from paprika. He demonstrated its relationship to antiscorbutic factor and named it hexuronic acid [894]. In 1933 the structure was elucidated by HAWORTH and HIRST [895] and confirmed by a synthetic route to D-ascorbic acid and L-ascorbic acid (REICHSTEIN, HAWORTH [897]). In the same year HAWORTH and SZENT-GYÖRGYI suggested the name be changed to L-ascorbic acid to reflect its antiscorbutic properties [898]. Both scientists were awarded the Nobel Prize in 1937 for their work on vitamin C.

10.3. Physical and Chemical Properties [883, 884]

A summary of physical properties of L-ascorbic acid is given in the following [899]:

Appearance	white, odorless, acidic taste
Formula	$C_6H_8O_6$
M_r	176.13
Crystalline form	monoclinic, usually plates, sometimes needles
mp	190 – 192 °C (decomp.)
Density	1.65 g/cm^3
Optical rotation	$[\alpha]_D^{25}$ in H_2O: +20.5° to +21° ($c = 1$)
	$[\alpha]_D^{20}$ in EtOH: +52° ($c = 0.5$) [900]
	$[\alpha]_D^{20}$ in MeOH: +49.5° ($c = 0.5$) [900]
pH	3 (5 g/L); 2 (50 g/L)
pK_1	4.17 (3-OH)
pK_2	11.57 (2-OH)
Redox potential	first stage: $E_0^1 = +0.127$ V (pH 5)
Solubility, g/mL	0.33 (H_2O)
	0.02 (absolute EtOH)
	0.01 (glycerol USP)
	0.05 (propylene glycol)
	insoluble in ether, benzene, oils, fats
UV	$\lambda_{max} = 245$ nm (acid solution)
	$\lambda_{max} = 265$ nm (neutral solution)
Spectral data	UV [901, 902]; IR [901, 903]; ^{1}H NMR [901, 904]; ^{13}C NMR [905, 906]; MS [907]

L-Ascorbic acid exists in at least five tautomeric forms [885], of which tautomer **1** represents crystalline L-ascorbic acid [908] and also predominates in aqueous solution at pH 2 [909]. The 2-OH and 3-OH groups are acidic. With bases ascorbic acid forms monobasic salts; the dibasic salts are unstable. In sodium ascorbate ($C_6H_7O_6Na$) and calcium ascorbate [$(C_6H_7O_6)_2Ca \cdot 2\,H_2O$] the metal atom is associated with the O atom in the 3-position [908]. The negative charge of the ascorbate monoanion is delocalized in a π-bonding system, which

explains the stability of its lactone ring toward alkali:

When boiled in methanolic potassium hydroxide L-ascorbic acid isomerizes to L-isoascorbic acid [910].

L-Ascorbic acid (**1**) is a strong reducing agent due to its enediol structure. Two-step oxidation of **1** proceeds via intermediate radical anion semidehydroascorbic acid (**4**) to dehydroascorbic acid (**2**) [911]. Semidehydroascorbic acid is a strong acid (pK = 0.45) and a radical scavenger; it reacts with itself, yielding **1** and **1a** [912], or with other free radicals.

The autoxidation of ascorbic acid to dehydroascorbic acid (**2**) is catalyzed by transition metals (e.g., Cu, Fe). In the presence of oxygen they form a ternary intermediate complex (e.g., **5**) which dissociates to dehydroascorbic acid (**2**), hydrogen peroxide, and the metal ion [913].

The autoxidative process accelerates above pH 7 and can be retarded by complexing the metal ions with chelating agents such as EDTA, metaphosphoric acid, citric acid, or oxalic acid. Treatment of ascorbic acid with oxygen in methanol containing activated carbon gives a syrupy methanol adduct, which on refluxing in methyl ethyl ketone forms dehydroascorbic acid (**2**) in 64 % yield as a crystalline dimer [914]. **2** is stable for several days at 4 °C in aqueous solution at pH 2.5 – 5.5 and can be quantitatively reduced back to ascorbic acid by, e.g., hydrogen sulfide, dithiothreitol, or cysteine [915]. Dehydroascorbic acid (**2**) still exhibits vitamin C activity, which is lost on irreversible opening of the lactone ring to give 2,3-diketogulonic acid [*3445-22-5*] (**6**).

Ascorbic acid readily undergoes degradation in aqueous solution under aerobic and anaerobic conditions (Fig. 16). The decomposition depends on pH, temperature, light, concentration, and heavy metal catalysts. The loss of ascorbic acid is often ten times higher in the presence of oxygen than the loss under anaerobic conditions. Final oxidation products are L-threonic acid (**7**) and oxalic acid. Anaerobic degradation proceeds to furfural (**8**) and CO_2 [883, 916].

In the absence of moisture and in darkness solid ascorbic acid is stable for a long time. Protection against oxidative degradation in aqueous applications is achieved by coating solid ascorbic acid with fats and polymers or by chemical substitution of the enediol hydroxyl groups (L-ascorbate 2-sulfate [917], L-ascorbate 2-phosphate [918], 2-*O*-methyl ascorbic acid [919]).

10.4. Analysis [886, 887]

Methods for determination of ascorbic acid are numerous. The first test was the biological assay: prevention or cure of scurvy in guinea pigs [920]. Despite being time consuming it is still used to measure the antiscorbutic activity of products. Chemical methods are mainly based on the reducing character or derivatization of ascorbic acid. They provide less expensive and faster assays, but do not distinguish between the different stereoisomers, and often other reducing substances interfere. Therefore, the selection of an analytical procedure for ascorbic acid in biological fluids, foods, and pharmaceutical preparations should be made carefully. Increased specificity can be achieved by using commercially available ascorbate oxidase. Ascorbic acid is selectively oxidized by this plant enzyme. HPLC allows rapid separation and detection of ascorbic acid and isoascorbic acid. High analytical specificity can be achieved by using a HPLC method with a post-column oxidation/reduction system in conjunction with UV, electrochemical (EC), or fluorometric measurement of ascorbic acid. HPLC and electrochemical methods are fully

Figure 16. Degradation of ascorbic acid

Table 31. Selected analytical procedures for ascorbic acid

Method, reagents	Notes	Ref.
Iodine	standard method in pharmacopeias, wide analytical range, not specific	[921]
Chloramine T	KI/starch, mixtures with sulfite, cysteine, glutathione, pharmaceutical preparations	[922]
2,6-Dichlorphenol-indophenol	standard redox reagent, automated procedures, poor specificity, dye instability	[923]
MTT	thiazolyl blue, ascorbic acid oxidase, marketed in kit form	[924]
2,4,6-Tris-(2-pyridyl)-*s*-triazine	colored iron complex, clinical method, determination of AA/DHA	[925]
2,4-Dinitro-phenylhydrazine	classical colorimetric method, interfering substances, clinical samples	[926]
Diazotized 4-methoxy-2-nitroaniline	pharmaceutical stability studies, automated serum and urinary analysis, blank correction	[927]
o-Phenylenediamine	official method, automatable, food analysis	[928]
Ascorbic acid oxidase	enzyme isolation, increase of specificity, food and clinical analysis	[929]
Electrochemical methods	specific oxidation at an electrode, automated procedure, 0.4 ng detection limit	[930]
GLC	trimethylsilyl derivatives of ascorbic acid, sugars and related substances	[931]
TLC	qualitative analysis of AA and degradation products	[932]
HPLC	detection by UV/refractive index, IAA/AA/diketo-gulonic/gluconic acid	[933]
HPLC, derivatization with DNPH	electrochemical detection, biological fluid analysis, IAA/AA, 2 ng detection limit	[934]
HPLC, reversed phase, ion pair	fluorescence detection, biological fluid analysis, AA/DHA/IAA, 10 ng detection limit	[935]

automatable and therefore suitable for routine assays or process control in production.

A selection of analytical methods is presented in Table 31.

10.5. Occurrence and Sources of Vitamin C

Ascorbic acid is considered to be an ubiquitous constituent of green plants. Ascorbic acid has not been encountered in yeast and prokaryotes, other than cyanobacteria, and it is not clear whether it occurs in colorless forms of plants [888]. During winter potatoes and cabbage were probably the most important sources of vitamin C for the Western population. Today, fresh fruits and vegetables are available all year. Storage and cooking partly destroy ascorbic acid [936].

The content of vitamin C varies in the different plant tissues. High concentrations are encountered in tropical fruits and in the leaves of gladiolus. The latter source was used industrially before the first chemical synthesis had been worked out. Some plants contain ascorbic acid in bound form: ascorbigen *(Brassica* species) [937] or elaeocarpusin [938].

In the animal kingdom ascorbic acid is also widespread, but in lower concentrations. The highest contents are found in the endocrinic organs (cow: hypophysis 126, adrenal gland 100–160 mg/100 g). Some species of animals, e.g., primates (including humans), guinea pig, flying mammals, some birds, and certain fishes and insects, cannot produce ascorbic acid.

The vitamin C content of some foods (in mg/100 g) follows [939]:

Fish	0–3	Asparagus	15–30
Liver, kidney	10–40	Beans	10–30
Meat (beef, pork)	0–2	Broccoli	70–160
Milk (human)	3–6	Brussels sprouts	90–150
Milk (cow)	1–2	Cabbage	30–60
Acerola	1300	Carrots	5–7
Apples	10–30	Cauliflower	60–80
Bananas	5–10	Oat, rye, wheat	0
Black currant	150–230	Parsley	170
Cherries	10	Peas	10–30
Guava	300	Peppers	125–200
Hawthorn berries	160–800	Potatoes	10–30
Lemons	50–80	Rice	0
Oranges	40–60	Spinach	50–90
Rose hips	1000	Tomatoes	10–30
Strawberries	40–90	Turnips	15–40

10.6. Biosynthesis [888]

Tracer experiments with radiolabeled sugars have revealed different biosynthetic pathways for ascorbic acid in animals and plants.

Animals convert D-glucose via glucuronic acid to vitamin C (Fig. 17). The biosynthesis includes an inversion of the carbon chain sequence, whereby C-1 and C-6 of D-glucose become C-6 and C-1, respectively, of ascorbic acid [940]. In scurvy-prone animals such as the guinea pig, the final step, which is catalyzed by L-gulonolactone oxidase, is missing. Administration of this enzyme enables guinea pigs to live on an ascorbic acid deficient diet [941]. Humans also lack L-gulonolactone oxidase. The ability to produce ascorbic acid was probably lost in the progress of evolution [942]. L-Gulonolactone oxidase resides in the liver of mammals and in the kidneys of other vertebrates (amphibians, reptiles, etc.) [943].

Biosynthesis in plants follows a noninversion pathway. D-Glucose [*50-99-7*] (**9**) is oxidized at C-2 to D-glucosone [*1854-25-7*] (**10**), epimerized at C-5 and finally oxidized at C-1. A speculative scheme of ascorbic acid synthesis in plants based on results of tracer studies is presented in Figure 18 [888]. Since plants also convert L-galactono-1,4-lactone to ascorbic acid very efficiently, an inversion-type pathway was postulated, too [944].

Metabolic degradation in plants leads to oxalic and tartaric acid [945], and in animals to CO_2, oxalic acid, C_5 aldonic acids, and undetermined products [946].

Biosynthesis is inhibited by deficiencies of vitamins such as vitamin A, E, or biotin, and is stimulated by xenobiotics and drugs (3,4-benzpyrene, barbiturates, etc.) [947].

10.7. Manufacture of Vitamin C

The first synthesis of L-ascorbic acid [895, 948] was accomplished before complete elucidation of its chemical structure. The starting material, L-xylosone (**11**), was treated with potassium cyanide, forming L-xylonitrile (**12**). After lactonization and enolization L-ascorbic acid (**1**)

Figure 17. Biosynthesis of ascorbic acid in animals

Figure 18. Biosynthesis of ascorbic acid in plants

was obtained in moderate yields (ca. 40 % from L-xylosone). However, this synthesis never attained economical importance, because of the lack of an easy and inexpensive access to L-xylosone.

About a year after publication of the first synthesis REICHSTEIN and GRÜSSNER described their route to L-ascorbic acid from the readily available C_6 sugar D-glucose [949]. This method remains the most important synthetic pathway for commercial manufacture. Today, ascorbic acid is produced by slight modifications of the scheme first devised in 1934.

10.7.1. Reichstein Synthesis [684]

The basic principle of the Reichstein synthesis is a sequence of easy, high-yield steps without cleavage or formation of a carbon – carbon bond. The essence of this pathway is reduction of C-1 of D-glucose and oxidation at positions 5 and 6. The chirality at C-2 and C-3 is preserved to give the L-*threo*-configuration at C-4 and C-5 of L-ascorbic acid.

The classical Reichstein – Grüssner synthesis starts with reduction of D-glucose (**9**) to D-sorbitol (**13**) by hydrogenation over a nickel catalyst. The microbiological oxidation of D-sorbitol [*50-70-4*] (**13**) to L-sorbose [*87-79-6*] (**14**) is carried out with *Acetobacter xylinum*. On treatment of L-sorbose (**14**) with acetone at low temperature in the presence of sulfuric acid, 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose [*17682-70-1*] (**15**) is formed.

The di-*O*-isopropylidenyl protection of the hydroxy-groups at C-2, C-3 and C-4, C-6 allows high-yield oxidation to di-*O*-isopropylidene-2-ketogulonic acid [*18467-77-1*] (**16**), without over-oxidation or other side reactions. The oxidation is carried out with potassium permanganate in alkaline solution. Treatment of **16** with hot water affords 2-keto-L-gulonic acid [*526-98-7*] (**17**), which is converted to L-ascorbic acid (**1**) by heating in water at 100 °C (20 % yield) or by esterification and treatment with sodium methoxide in methanol followed by acidification with hydrogen chloride, yielding ca. 70 % of **1**. The overall yield of ascorbic acid from D-glucose is 15 – 18 %.

10.7.2. Industrial Manufacture by the Reichstein Route

The development of REICHSTEIN's classical procedure into an industrial process is marked by great efforts to improve each reaction step. As a result of many technical and chemical modifications each step gives over 90 % yield. The overall yield of ascorbic acid from D-glucose is now ca. 60 %.

d-Sorbitol. The catalytic hydrogenation of D-glucose (**9**) to D-sorbitol (**13**) is accomplished at high pressures and elevated temperatures in the presence of a Raney nickel catalyst (see bottom of page).

The hydrogenation is carried out in batch or continuous operations and affords almost quantitative yields with minimal formation of D-mannitol and L-iditol. After removal of the catalyst, the sorbitol solution is employed in fermentation without any further purification. Therefore, manufacturers of ascorbic acid make high demands on the quality of D-glucose (**9**); crystalline dextrose or purified starch hydrolysates are used.

The cathodic and microbiological reduction of D-glucose (**9**) to D-sorbitol (**13**) have also been reported [950].

l-Sorbose is obtained in the pyranose form by microbiological oxidation of sterile aqueous solutions of D-sorbitol (**13**) in batch or continuous operations in the presence of air. The most frequently used strains belong to the *Gluconobacter oxydans* family, which converts D-sorbitol (**13**) to L-sorbose (**14**) with more than 90 % efficiency. Large-scale fermentations have to be carried out at pH 4 – 6 and at 30 – 35 °C under sterile conditions to avoid loss of product during oxidation and work-up by filtration and crystallization.

2,3 : 4,6-Di-O-isopropylidene-α-l-sorbofuranose. The protection of the 2,3- and 4,6-

hydroxyl groups by forming cyclic ketals is achieved in acetone with excess sulfuric acid as catalyst and dehydrating agent, generally at low temperatures (e.g., 4 °C). In the final reaction mixture 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (**15**) is obtained as main product. Byproducts are 2,3-*O*-isopropylidene-α-L-sorbofuranose and 1,2-*O*-isopropylidene-α-L-sorbopyranose. After neutralization, excess acetone is recovered by distillation. 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (**15**) is extracted from the aqueous solution with aromatic solvents (e.g., toluene). The remaining monoisopropylidenesorboses are also recovered from the aqueous solution and returned to the process.

2,3 : 4,6-Di-O-isopropylidene-2-keto-l-gulonic acid. Originally, the oxidation of 2,3 : 4,6-di-*O*-isopropylidene-α-L-sorbofuranose (**15**) to 2,3 : 4,6-di-*O*-isopropylidene-2-keto-L-gulonic acid (**16**) was performed at elevated temperatures in dilute sodium hydroxide with $KMnO_4$, yielding ca. 90 % of product. Much less expensive oxidation methods are applied in modern continuous processes: sodium hypochlorite, electrochemical oxidation, or catalytic air oxidation.

Oxidation with hypochlorite in the presence of catalytic amounts of nickel chloride or sulfate at 60 °C yields >93 % of **16**. The active oxidant is presumably nickel peroxide [951].

Electrochemical oxidation is performed with nickel or nickel oxide electrodes in alkaline solution [952, 953]. Hydrogen, evolved at the cathodes, can be used for hydrogenation of D-glucose. It can be advantageous to stop electrochemical conversion to **16** at ca. 90 % to avoid a drop in selectivity at the end of electrolysis. Oxidation can be completed with sodium hypochlorite solution. At the end of the electrooxidation, selectivity can be improved by electrolytic cells with high electrode surfaces, such as Swiss-roll cells [954] or cells with three-dimensional electrodes [955].

Alternatively, the oxidation has been performed by using air or oxygen and a metal catalyst in alkaline solution. Good yields are achieved with palladium or platinum on carbon [956, 957]. The reaction product 2,3 : 4,6-di-*O*-isopropylidene-2-keto-L-gulonic acid (**16**) is isolated by acidification and precipitation as the monohydrate.

l-Ascorbic acid. The conversion of 2,3 : 4,6-di-*O*-isopropylidene-2-keto-L-gulonic acid (**16**) to L-ascorbic acid (**1**) is achieved by two different procedures:

1) Deprotection to give 2-keto-L-gulonic acid (**17**), followed by esterification with methanol and base-catalyzed cyclization
2) Acid-catalyzed cyclization to ascorbic acid directly from the protected or released 2-keto-L-gulonic acid.

The starting material for base-catalyzed reactions is methyl 2-keto-L-gulonate [*3031-98-9*] (**18**), prepared by treatment of the acid **16** with acidic methanol. Finally, reaction of the methyl ester **18** with sodium hydrogencarbonate or sodium acetate affords sodium ascorbate in high yield [958, 959].

The first acid-catalyzed route to ascorbic acid was published only few years after discovery of the Reichstein process [960, 961]. Today, the industrial process is performed with an inert solvent (e.g., trichloromethane or toluene) in the presence of hydrochloric acid. The advantage of this method is that ascorbic acid precipitates from the mixture as it is formed, minimizing decomposition during reaction. The crude product is obtained by filtration in high yield and high purity. After dissolution of crude ascorbic acid in water, impurities are removed by refining with activated carbon, decolorizing resins, or ionexchange resins, followed by crystallization.

Environmental Aspects. The economical efficiency of the Reichstein synthesis is strongly influenced by environmental protection costs.

Wastewater is fed into a sewage plant. The discharged COD load is similar to the amount of ascorbic acid produced. Most constituents (sugar derivatives) are easily biodegradable. Effluents containing ketalized sugar derivatives have to be pretreated to hydrolyze nondegradable ketals. Loss of nickel catalyst in wastewater is nearly quantitatively eliminated by filtration and adsorption on ion-exchange resins. The inorganic load consists of sodium chloride and sodium sulfate.

Contaminations in exhaust gases are mainly removed by absorption in water scrubbers.

Gases containing water-insoluble compounds such as chlorinated solvents are purified by adsorption on activated carbon and/or by low-temperature condensation.

Distillation residues are disposed of by incineration. Solid residues are mainly sewage sludge, spent carbon, and filter aids.

10.7.3. Other Methods for Production of Ascorbic Acid [879, 885, 889]

All syntheses of L-ascorbic acid (**1**) are partial syntheses in which the chirality at C-4 and C-5 is derived from naturally occurring sugars. Starting material is most frequently cheap D-glucose (**9**), and to some extent galactose and galacturonic acid obtained from natural sources. Syntheses involving the coupling of a C_1 fragment and a C_5 fragment (e.g., L-arabinose [962]) or a C_2 fragment and a C_4 fragment are less important, but useful for the preparation of radiolabeled derivatives and analogues of ascorbic acid (review in [879]). D-Glucose (**9**) is converted to L-ascorbic acid (**1**) either by inversion of the carbon chain sequence (C-2/C-3 of glucose become C-5/C-4 of ascorbic acid) or by inversion of the configuration of C-5. A schematic overview of selected partial syntheses of L-ascorbic acid is given in Figure 19.

Many efforts have been made to reduce production costs by optimizing and shortening the various reaction routes. These attempts include the combination of chemical and microbiological reaction sequences, direct chemical oxidations (avoiding the use of protecting groups), enzymatic catalysis, the use of genetically modified microorganisms or plant tissues, and cofermentations. Main emphasis in the last decade was on the development of the fermentative transformation of D-glucose (**9**) to 2-keto-L-gulonic acid (**17**) via D-sorbitol (**13**), L-sorbose (**14**) or 2,5-diketogluconic acid [*2595-33-7*] (**28**), and the direct conversion of D-glucose (**9**) to L-ascorbic acid (**1**) by mutagenized microalgae. However, the Reichstein synthesis still predominates in commercial production, although it is reported that a single fermentation step to 2-keto-L-gulonic acid (**17**) has already reached production scale [963].

Synthesis via l-Sorbose (Fig. 19 B). *Modification of Protecting Groups.* The replacement of acetone as a protecting agent for the oxidation of L-sorbose (**14**) has been intensively studied in the past [885]. However, the use of other reagents such as formaldehyde, benzaldehyde, cyclohexanone, etc. is not economic and little attention is paid to further improvements of these methods. Syntheses using partly protected L-sorbitol [964] or L-sorbose (e.g., methylsorboside [965]) are also not viable alternatives.

Chemical Oxidation. Direct oxidation of L-sorbose (**14**) to 2-ketogulonic acid (**17**) has been tried by many authors. Best results are obtained by catalytic oxidation with noble-metal catalysts, promoted by heavy metals such as bismuth or lead. The reaction however is not sufficiently selective, the catalyst is rapidly deactivated, and published yields (up to 87 %) are hardly reproducible [966].

Microbiological Oxidation. Fermentative production of 2-keto-L-gulonic acid (**17**) from L-sorbose (**14**) with microorganisms of the genera *Pseudomonas, Bacillus, Gluconobacter*, etc. is the subject of numerous patents. The biosynthesis of 2-keto-L-gulonic acid (**17**) in bacteria proceeds via L-sorbosone [*49865-02-3*] (**19**). L-Idonic acid, reported earlier to be an intermediate, is probably a degradation product of 2-keto-L-gulonic acid (**17**) [967].

Oxidation can be accomplished with single microorganisms, mixed-culture fermentations, or by enzymatic catalysis. Continuous improvements to these methods over the last decades by using bioengineering techniques has led to remarkable results. A Chinese patent claims a process which comprises the mixed-culture fermentation of L-sorbose (**14**) to 2-keto-L-gulonic acid (**17**) in yields of 70 – 80 % [968]. Even better results are obtained by fermentation of L-sorbose (**14**) with *Pseudogluconobacter saccharoketogenes/Bacillus megaterium* and supplementing the culture medium with rare earth elements (yield 86 %); isolation of the crystalline free acid from the fermentation broth gave an overall yield of ca. 70 % [969]. Further improvement is achieved when D-sorbitol (**13**) is used as starting material instead of L-sorbose (**14**). Mixed-culture fermentation of D-sorbitol (**13**) with strains of *Gluconobacter suboxydans* and *Gluconobacter oxydans* results in yields of 75 – 90 % [970]. A purification method for 2-keto-L-

Figure 19. Synthetic pathways to L-ascorbic acid

gulonic acid (**17**) is given in [971]. Once scaled up, the microbiological oxidation of D-sorbitol (**13**) or L-sorbose (**14**) to 2-keto-L-gulonic acid (**17**) will enable a cheaper production route to L-ascorbic acid.

In a wider sense all these reaction sequences via L-sorbose represent modifications of the Reichstein process, and the final step – conversion of 2-keto-L-gulonic acid (**17**) to ascorbic acid (**1**) – still has to be performed chemically.

Synthesis via d-Glucuronic Acids (Fig. 19 C). Other routes from D-glucose (**9**) to L-ascorbic acid (**1**) start with oxidation at C-6,

leading to D-glucuronic acid derivatives. The C-1 aldehyde group is reduced in subsequent steps. Key intermediates of these syntheses are the ketolactone (**22**) and L-gulonolactone [*1128-23-0*] (**24**).

In the synthesis of BAKKE and THEANDER (**9** → **21** → **22** → **25** → **1**) L-ascorbic acid is obtained in 28 % overall yield from D-glucose [972]. A modification of this method has been published by KITAHARA, who synthesized ketolactone (**22**) from D-glucuronolactone [*32449-92-6*] (**23**) [973]. Due to low yields and high reagent costs these syntheses have not attained industrial significance.

A shorter production route to L-ascorbic acid proceeds via L-gulonolactone (**24**), which is obtained by hydrogenation of D-glucuronolactone (**23**) [974]. L-Gulonolactone (**24**) can be oxidized chemically [975] and microbiologically [976] to 2-ketogulonic acid (**17**) in good yield, or directly converted to L-ascorbic acid (**1**) with L-gulonolactone dehydrogenase [977]. To compete with the Reichstein process these syntheses require cheap access to D-glucuronolactone (**23**). However, **23** is obtained from protected glucose [978] or starch [979] only in low yields.

Synthesis via Gluconic Acids (Fig. 19 A). In this pathway D-glucose is converted to L-ascorbic acid without carbon-chain inversion, and the correct configuration at C-5 is achieved by a oxidation/reduction sequence. Key intermediates of these pathways are 5-ketogluconic acid [*5287-64-9*] (**26**) and 2,5-diketogluconic acid (**28**).

Microbiological oxidation of D-glucose to 5-keto-D-gluconic acid (**26**) is carried out with strains of *Acetobacter suboxydans* in almost quantitative yields. **26** is reduced by catalytic hydrogenation to a mixture of D-gluconic and L-idonic acid [*1114-17-6*] (**27**) (77 %). Fermentation of **27** with *Pseudomonas* strains yields 2-keto-L-gulonic acid (**17**) (90 %) [885]. The lack of a selective reduction method for **26** seems to be the reason that little attention has been paid to further development of this synthesis.

2,5-Diketogluconic acid (**28**) is efficiently produced from D-glucose (**9**) by several species of *Acetobacter*, *Gluconobacter*, or *Erwinia* [980]. Subsequent chemical ($NaBH_4$) or microbiological reduction converts **28** to 2-ketogulonic acid (**17**) [885]. An alternative chemical route proceeds via the 5,5-dimethyl ketal of **28** and 5-keto-L-ascorbic acid (**29**) to **1** [981]. **29** and its 5,5-dimethyl ketal exhibit antiscorbutic activity. The microbiological process → **17** has been optimized by introducing a two-stage fermentation method with mutant strains of Erwinia sp. and *Corynebacterium sp.* (73 % overall yield from glucose) [982]. The mutagenic treatment is necessary to repress the gene for 2-keto-D-gluconate formation, because the isolation of **17** from a mixture containing 2-keto-D-gluconate is difficult [983]. Addition of nitrate to the culture medium has a stimulative effect on the production of **17** [984]. Further simplification of the process by combining the relevant traits of *Erwinia sp.* and *Corynebacterium sp.* into a single organism was investigated by two different research groups, but the results obtained still remain far from industrial application [985].

Synthesis via d-Galacturonic Acid (Fig. 19 E). This approach is similar to synthesis via D-glucuronic acid [*6556-12-3*] (**20**): inversion of carbon-chain sequence, similar reaction conditions, and difficult access to low-cost starting material. The differing chirality at C-4 of D-glucuronic acid (**20**) is lost in the final reaction step (C-3 of L-ascorbic acid).

D-Galacturonic acid [*685-73-4*] (**31**) is obtained by enzymatic hydrolysis of pectic acid [885] or by chemical transformation of D-galactose [*59-23-4*] (**30**) which is available from lactose-containing whey [986]. Catalytic reduction of the aldehyde group affords L-galactonic acid [*28278-08-2*] (**32**), which is transformed to L-ascorbic acid (**1**) by fermentation with *Candida sp.* [987] or by chemical oxidation to **33** and subsequent cyclization to **1** [885].

Synthesis by Microalgae (Fig. 19 D). Direct synthesis of L-ascorbic acid (**1**) from D-glucose (**9**) can be achieved with mutagenized microalgae of the genus *Chlorella* [988]. Up to now yield and concentration are too low for industrial application, but the L-ascorbic acid (**1**) enriched biomass obtained may be useful as an aquaculture fish feed or feed additive.

10.8. Absorption and Metabolism

Ascorbic acid is readily absorbed intestinally and to a lesser extent in the mouth and stomach. The absorption rate of low supplemental doses is up to 80 %; for example, 75 % is absorbed at an oral intake of 1 g. There is an inverse relationship between supplement and absorption rate because of limited intestinal absorption capacity. The absorption rate is lowered to ca. 20 % at an oral intake of 5 g [989]. Excess ascorbic acid is excreted unaltered in the urine.

Vitamin C is the most abundant water-soluble antioxidant in the body. The polarity that encourages its presence in aqueous fluids also hinders its passage across the hydrophobic cell membrane. This, and the high concentrations within the cell, makes it almost certain that the form of transport of ascorbic acid is active and facilitated, i.e., requiring membrane carriers such as sodium ions [990].

Although widely distributed in the body, ascorbic acid is concentrated in adrenal and pituitary glands, in the brain, eye lens, and in leukocytes [991]. A dosage of ca. 60 mg of ascorbate per day is necessary to create and maintain a body pool of 1500 mg, which protects against scurvy for at least 30 d. However, the body pool can be expanded to 2300 – 2800 mg by 200 mg/d doses [992].

The main metabolites of ascorbate in the human body are oxalate, dehydroascorbic acid, 2,3-diketogulonic acid and ascorbic acid 2-sulfate. Large intakes of ascorbic acid do not induce higher levels of oxalate because humans are not able to indefinitely increase the metabolism of ascorbate.

10.9. Medical Aspects of Vitamin C

The most significant chemical property of L-ascorbic acid is its oxidation to dehydro-L-ascorbic acid. This reversible oxidation is the basis for many of its known physiological activities.

A number of enzymes are stimulated by ascorbic acid. Compared with other reducing agents vitamin C shows the greatest stimulation of dioxygenases that contain prosthetic Fe^{2+} and monooxygenases with prosthetic Cu^{+}. Dioxygenases are responsible for several hydroxylation reactions. In collagen synthesis, proline and lysine are hydroxylated on the growing polypeptide chain. Many of the clinical signs of scurvy are explained by defects in collagen synthesis. Keeping iron in dioxygenase in its required reduced form seems to be the role of ascorbic acid [992].

The requirement for ascorbic acid as a cofactor in hydroxylation reactions is also suggested in the biosynthesis of norepinephrine from dopamine, of carnitine, of homogentisic acid, of 5-hydroxytryptophan, and of 3,4-dihydroxyphenylalanine.

Ascorbic acid is an essential cofactor for the activation of peptidylglycine α-amidating monooxygenase. It provides reducing equivalents to the copper-containing enzyme which is responsible for biosynthesis of neuropeptides and endocrine peptides. Thus, ascorbic acid plays an important role in the proper functioning of the nervous and endocrine systems [993].

Much literature deals with the relationship between vitamin C and the common cold. A high vitamin C level in the body does not decrease the number of incidences of the common cold. However, it has consistently decreased the duration of cold episodes and the severity of symptoms. Ascorbic acid seems to decrease inflammatory effects by reduction of oxidizing compounds released from activated leukocytes [994].

Vitamin C appears to play many important roles in protecting the body against cancer. The ability of ascorbic acid to inhibit formation of carcinogenic nitrosamines in the stomach is the best documented cancer-protecting effect of vitamin C [995]. It takes part in the protection of DNA and lipid membranes from oxidative damage, an important factor in cancer incidence. Vitamin C in connection with other antioxidants may also have beneficial effects on immune response, thereby reducing cancer risk by enhancing tumor surveillance by the immune system [996].

Ascorbic acid serves as an intracellular and extracellular quencher of free radicals and oxidants. Together with other antioxidants such as carotenes, glutathiones or vitamin E, ascorbic acid acts as a scavenger of oxygen species. In contrast to redox reactions, in which vitamin C donates two electrons, in the inactivation of highly reactive free radicals, ascorbic acid do-

nates only one electron. The reduction of tocopheroxy radical to tocopherol, retaining the level of vitamin E in tissues, follows this pathway. Vitamin C reduces vitamin E radical not only in homogeneous solution but also in liposomal membrane systems [997, 998].

Vitamin C influences the catabolism of cholesterol. Studies in humans show that for individuals with high total cholesterol concentrations a supplement of ascorbic acid may have a beneficial effect. These results suggest an inverse relationship between vitamin C level in the body and cardiovascular diseases [999].

Ascorbic acid possesses an essential physiological function in iron absorption. It enhances the absorption in a logarithmic fashion. A dosage of 25 – 50 mg vitamin C per meal secures an optimum promoting effect on absorption [1000]. Despite some warnings, the ingestion of large quantities of ascorbic acid does not result in calcium oxalate stones, increased uric excretion, impaired vitamin B_{12} status, iron overload, systemic conditioning (dependence after prolonged ingestion of high doses), or increased mutagenic activity in healthy individuals [1001]. High doses of ascorbic acid over long periods of time do not lead to any side effects. In several clinical studies daily intakes up to 10 g were applied for several years without any adverse effects [1002].

Vitamin C is an essential nutrient for the maintenance of human health. The main application is the prevention and therapy of scurvy. L-Ascorbic acid supports wound healing and it enhances the body's immune response in preventing and fighting infection. It has been suggested that L-ascorbic acid is helpful in preventing cancer and cardiovascular diseases. A daily supplement to enhance iron-absorption from food is also recommended in treating anemia [1003].

Some high risk groups, such as smokers, elderly people, diabetics, and alcoholics, have a lower vitamin C status than the rest of the population. Pregnant and lactating women, women taking oral contraceptives, sportsmen, sick and stressed people require a higher daily intake of vitamin C. In these cases, supplementary vitamin C is beneficial.

The current recommended ascorbic acid intakes of 60 mg/d (United States, European Community) [1004, 1005] or 75 mg/d (Germany) [1006] are based only on the prevention of scurvy and on the urinary excretion threshold. The optimum amount of ascorbic acid for human health is under discussion, and many experts recommend a much higher daily intake.

10.10. Industrial Uses [890–892]

The chemical properties of L-ascorbic acid provide a wide range of industrial applications. About one-third of total production is used for vitamin preparations in the pharmaceutical industry. The rest is mainly applied as an additive to food and feed to enhance product quality and stability.

L-Ascorbic acid is an active component in a variety of pharmaceutical products, including multivitamin preparations, tablets, syrups, elixirs, and effervescent tablets. Solid dosage forms are quite stable. In liquid formulations ascorbic acid is subject to oxidative decomposition and interaction with other ingredients.

The largest field of application is in the food industry, particularly in the processing of meat, fruits, and flour. The antioxidant and physiological vitamin activity of ascorbic acid is used to preserve foods, avoiding undesirable odors, flavors, and colors due to oxidative degradation, to enhance the nutrient value, or to improve processing:

1) Inhibition of nitrosamine formation in cured meat products
2) Protection from enzymatic browning in processed fruits and vegetables
3) Nutritional restoration and fortification of foods and beverages
4) Improvement of flour and dough quality
5) Retardation of oxidative rancidity in fats and oils
6) Increased clarity of wine and beer
7) Synergistic activity in applications with other antioxidants (e.g., tocopherols)

In the United States, ascorbic acid may not be added to fresh meats, because it prevents discoloration and may thus give a false appearance of freshness. Ascorbic acid, its salts, and ascorbyl palmitate are registered food additives in the European Community and classified as generally recognized as safe (GRAS) substances by FDA.

Ascorbic acid or the more stable 2-sulfate are used in fish farming to prevent scurvy and enhance immune response.

The use of ascorbic acid in plant applications (improvement of seed germination, ozone protection, harvesting aid, disease resistance, growth regulation) is limited by its economics.

Further use in the polymer, photographic, and cosmetic industries, etc. is less important.

10.11. Economic Aspects

Total demand for ascorbic acid in 1995 is estimated at 60 000 t/a. Since 1980 world production has increased by 50 %. After a long consolidation period at ca. 24 DM/kg in Europe and $ 15 in overseas trade, the price of ascorbic acid began to fall in 1995 because of the appearance of new suppliers, especially from China. The development of world market price is as follows:

1954	36 €/kg	1980	10 €/kg
1957	20 €/kg	1982	12 €/kg
1964	8 €/kg	1993	12.50 €/kg
1974	9 €/kg	1995	10 €/kg

Principal manufacturers include: Hoffmann-La Roche; Dalry (United Kingdom), Belvidere (United States); Takeda Ind. Chem., Osaka (Japan), Wilmington (United States); Merck, Darmstadt (Germany); BASF, Grenaa (Denmark); Pliva, Zagreb (Croatia); and several Chinese companies, including Northeast General Pharmaceutical Factory, Sunve Shanghai No. 2, Xing Xang Pharmaceutical Factory, Jingshu Pharma, and Jiang Xi.

The bulk of production is sold as ascorbic acid. However, specialities such as salts, esters (ascorbyl palmitate, sulfate), coated ascorbic acid, and granulated acid for direct compression are becoming increasingly important.

11. Pantothenic Acid

11.1. Introduction

The structure of pantothenic acid, [(*R*)-(+)-*N*-(2,4-dihydroxy-3,3-dimethyl-1-oxobutyl)-β-alanine] (**1**), is characterized by a carboxyl group, a primary and a secondary hydroxyl group, an ω-peptide bond, and a chiral center. Only the *R* enantiomer occurs in nature; the *S* form has no vitamin activity.

11.2. History

Pantothenic acid was discovered by WILLIAMS in 1931 as a growth factor for microorganisms [1012]. In 1938, it was isolated in a purity of ca. 40 % from sheep liver [1013]. It was then identified with the aid of two "active factors," required for normal growth in rats [1015] and to prevent dermatitis in chickens [1014]. The name pantothenic acid results from its ubiquitous distribution (Greek: from everywhere) [1016].

11.3. Physical and Chemical Properties

Pantothenic acid (**1**) is a hygroscopic oil which is instable in acidic or alkaline solution. The commercial form is the calcium salt. The sodium salt and the corresponding alcohol, (*R*)-panthenol, are used in special pharmaceutical formulations.

Calcium and sodium (*R*)-pantothenate are white powders (*mp* ca. 200°C, decomp., and 160 – 165°C, respectively). The sodium salt is hygroscopic.

(*R*)-Panthenol is a colorless, viscous oil. Other physical data are presented in Table 32.

11.4. Occurrence

Pantothenic acid (**1**) is widely distributed in plant and animal tissues in varying concentrations. Liver, kidneys, egg yolk, muscle, brain, yeast, rice and wheat bran, green leafy vegetables, and legumes are especially rich sources of this vitamin (Table 33).

Table 32. Physical data of pantothenic acid and some of its derivatives

Compound	Empirical formula	M_r	$[\alpha]_D^{20}$ ($c = 4$, water)	Solubility in		
				water	ethanol	ether
(*R*)-Pantothenic acid	$C_9H_{17}NO_5$	219.2	+ 37.5	readily soluble	soluble	slightly soluble
Calcium (*R*)-pantothenate	$(C_9H_{16}NO_5)_2Ca$	476.5	+ 27.0	readily soluble	poorly soluble	insoluble
Sodium (*R*)-pantothenate	$C_9H_{16}NO_5Na$	241.2	+ 27.5	readily soluble	slightly soluble	insoluble
(*R*)-Panthenol	$C_9H_{19}NO_4$	205.3	+ 30.5	readily soluble	readily soluble	poorly soluble

Table 33. Occurrence of pantothenic acid in foods according to the German Bundeslebensmittelschlüssel (BLS), 1990 and Souci, Fachmann, Kraut (SFK) 1989 [1017]

Food	Content, mg/100 g		
	BLS	[1018]	SFK
Fruit			
Apple	0.1		0.1
Strawberries	0.3		0.3
Oranges	0.25		0.24
Vegetables			
Broccoli	1.3		1.29

Pantothenic acid mainly occurs in nature in the bound form as a component of coenzyme A. It is not formed in the human or animal organism. Only the conversion of pantothenic acid to the metabolically active molecule coenzyme A is biosynthetically possible. In contrast, most microorganisms are capable of synthesizing pantothenic acid from pantoic acid and β-alanine.

(*R*)-Panthenol does not occur in nature. It is rapidly oxidized to pantothenic acid by warm-blooded animals [1019]. In feeding experiments on chickens, (*R*)-panthenol exhibits ca. 60 % of the vitamin activity of an equimolar amount of calcium (*R*)-pantothenate [1020].

11.5. Biosynthesis

The biosynthesis of pantothenic acid proceeds via enzyme-catalyzed condensation of pantoic acid with β-alanine in the presence of adenosine triphosphate. The intermediate enzyme complex of pantothenic acid synthetase, pantoic acid, and AMP has been thoroughly studied [1021].

The biosynthesis of pantoic acid (**2**) branches off from that of valine at the 2-oxo-3-methylbutyric acid (**3**) stage [1022]. The introduction of a hydroxymethyl group by means of 5,10-methylenetetrahydrofolic acid [1023] results in 4-hydroxy-3,3-dimethyl-2-oxobutyric acid (**4**), which is enzymatically reduced to **2** with formation of an asymmetric center.

At least four pathways are known for the biosynthesis of β-alanine (**5**):

1) Hydrogenation and hydrolysis of uracil (**6**) via β-ureidopropionic acid (in *Chlostridium uracilicum*) [1024]
2) Decarboxylation of L-aspartic acid (**7**) [1025]

3) Oxidative degradation of spermine or spermidine (**8**) (in *Pseudomonas aeruginosa*) [1026]
4) Transamination of malonylaldehydic acid (**9**) with amino acids, especially with glutamic acid in mammals and microorganisms [1027]

11.6. Production

The starting materials for the large-scale production of calcium (*R*)-pantothenate, the commercial form of pantothenic acid, are (*R*)-pantolactone and calcium β-alaninate.

Pantolactone. Racemic pantolactone (**10**) can be produced in a yield of ca. 90 % from isobutyraldehyde, formaldehyde, and hydrogen cyanide without the isolation of intermediates [1028]. The intermediates are 3-hydroxy-2,2-dimethylpropanal (**11**) and 2,4-dihydroxy-3,3-dimethylbutyronitrile (**12**). Saponification of **12** with strong acids directly produces the lactone (**10**), which can be isolated by extraction and/or distillation.

Several processes have been developed for the preparation of optically active (*R*)-pantolactone (**13**): (1) resolution of racemates with recycling, (2) asymmetric hydrogenation, and (3) microbiological synthesis.

Diastereomeric salts or amides of pantoic acid can be separated by fractional crystallization. The separation can be achieved with alkaloids [1029] and with synthetic chiral amines [1030]. Amines such as dehydroabietylamine (from rosin) [1031] and (+)-3-aminoethylpinane (from (−)-α-pinene) [1032], which are easily obtainable from inexpensive starting materials, are especially suited to industrial application.

Frequently, the enantiomers are separated by fractional crystallization after alternately seeding with the *R* or *S* form. Such processes are known for pantolactone [1033], acetylpantolactone [1034], and salts of pantoic acid [1035].

Racemization and recycling of undesired (*S*)-pantolactone are achieved either by heating with aqueous NaOH for several hours at 150°C to give sodium pantoate, or in the presence of strongly basic amines or alkoxides [1036].

Alternative processes for (*R*)-pantolactone begin with the corresponding 2-oxolactone (**16**), which is obtainable by oxidation of **10** [1037] or of the 2-aminolactone **14** [1038], or by reaction of dimethylpyruvic acid (**15**) with formaldehyde [1039]. 2-Oxopantolactone can be enantioselectively hydrogenated to (*R*)-pantolactone (**13**) microbiologically [1040] or catalytically with optically active rhodium complexes.

The biphosphines **17** and **18**, obtainable from 4-hydroxyproline, are the preferred chiral ligands [1041].

17

18

A large number of microbiological processes for the production of (*R*)-pantolactone have been described [1042]. For instance, stereoselective enzymatic oxidation of racemic pantolactone (**10**), followed by asymmetric reduction of the resulting 2-oxolactone, affords quantitative conversion to (*R*)-pantolactone [1043]. However, these processes have not yet gained economic importance.

β-Alanine. Two processes are mainly used for the industrial synthesis of β-alanine (**5**).

The addition of ammonia to acrylonitrile (**19**) at 20 – 30 bar and ca. 125°C yields β-aminopropionitrile (**20**), which is hydrolyzed with sodium hydroxide solution to give sodium β-alaninate [1044]. After acidification with sulfuric acid, evaporation, and extraction of the residue with methanol, crystalline β-alanine is obtained [1045].

Starting with acrylic acid (**21**), the addition of ammonia directly produces β-alanine with the avoidance of salt formation [1046].

Until now, microbiological processes [1047] have not been used on a large scale.

Aqueous solutions of β-alanine are obtained by chromatography on weakly acidic cation

exchangers and, more recently, by electrodialysis of aqueous alkaline solutions [1048].

β-Alanine is converted to the corresponding calcium salt (**22**) before further reaction with (*R*)-pantolactone. After neutralization of **5** with $Ca(OH)_2$ in water, filtration, and drying, a product is obtained which is free of water-insoluble components. Consequently, it fulfils the strict quality requirements of Pharm. Eur. II and USP XXII.

Pantothenic Acid. Calcium (*R*)-pantothenate is obtained by the reaction of calcium β-alaninate with (*R*)-pantolactone in boiling methanol or ethanol. Depending on the crystallization and drying conditions, three solventless polymorphous forms, two solvates, and an amorphous product can be isolated [1049]. Hygroscopic prisms with four moles of methanol and one mole of water are formed on crystallization from 90 % aqueous methanol at 0°C. Drying of these prisms at 80°C and 30 mbar produces X-ray amorphous calcium (*R*)-pantothenate while maintaining the crystal form.

Calcium (*R*)-pantothenate can be produced by seeded crystallization in 90 % aqueous methanol by exploiting the higher solubility of the racemate compared with the solvates of the enantiomers [1050]. Racemization of the *S* form is achieved with sodium methoxide in anhydrous methanol [1051].

Sodium (*R*)-pantothenate is isolated by reacting sodium β-alaninate with (*R*)-pantolactone in methanol or ethanol (1 h, 65°C) [1052]. On cooling, it crystallizes in the form of square platelets (*mp* 160 – 165°C) and is highly hygroscopic.

Panthenol. (*R*)-Pantolactone reacts with 3-amino-1-propanol at 70°C (2 h) to give (*R*)-panthenol [1053]. On distillation at 170°C and 10^{-3} bar, a colorless product is obtained which meets the requirements of Pharm. Eur. II and USP XXII.

11.7. Metabolism and Importance for the Organisms; Coenzyme A and its Precursors

Pantothenic acid exhibits its biological activity as a component of coenzyme A (**23**) [1054] and of some peptide coenzymes [1055] which, in the form of energy-rich thiol esters, participate in the metabolism of carboxylic acids, especially of acetic acid.

Pantothenic acid (active form: acetyl coenzyme A and derivatives) occupies a central position in intermediary metabolism (Fig. 20). It is involved in numerous biochemical reactions and enzymatic processes and, via coenzyme A, is of fundamental importance in the entire metabolism:

1) Reactive esters are formed from unreactive fatty acids
2) Degradation of carbohydrates, fats, and amino acids occurs mainly at the acetyl coenzyme A stage
3) Acetyl coenzyme A provides active acetate groups for the biosynthesis of fatty acids, phosphatides, and sterols (cholesterol, bile acids, steroid hormones)
4) Acetyl groups bound to coenzyme A enter the citric acid cycle (energy producing oxidative degradation of substances to CO_2, H_2O, and synthesis of ATP)
5) Acetyl coenzyme A transfers the acetyl group to certain acceptors (e.g., formation of the transfer agent acetylcholine at the nerve ends)
6) Amino sugars are acetylated in the synthesis of mucopolysaccharides (cartilage), hyaluronic acid (connective tissue), and other (mesenchymal) skeletal substances
7) Acetyl coenzyme A supplies the acetyl groups for acetylation reactions that are involved in the detoxification of foreign substances (e.g., chemotherapeutic agents, sulfonamides)
8) Coenzyme A participates in the synthesis of the porphyrin skeleton of hemoglobin by providing succinic acid in an activated form

Further physiological functions in the organism are attributed to pantothenic acid. It is important for:

1) Formation and normal function of body tissues
2) Maintaining the resistance of mucous membranes to infections
3) The optimal course of metabolic processes, especially in the skin and epithelial tissue
4) Promotion of growth and pigmentation of the hair

The absorption of pantothenic acid in the intestine proceeds rapidly, absorption being mainly by diffusion, less by active transport [1056]. It is distributed among practically all the cells in the entire body (tissue concentrations between 2 and 45 µg/g).

Especially high concentrations of coenzyme A are found in the liver, kidneys, adrenals, and erythrocytes. The pantothenic acid present in blood serum is bound to plasma proteins. In the human organism, pantothenic acid is hardly metabolized. Absorption and elimination of this vitamin are almost in balance (ca. 70 % of the pantothenic acid absorbed is excreted unchanged in the urine and ca. 30 % in the feces) [1057]. Thus, the vitamin status can be determined from either the plasma level or the rate of excretion in the urine.

The structural elucidation of coenzyme A in 1954 [1054] was confirmed by its synthesis in 1959 [1058]. The key product was the derivative (**27**) of adenosine diphosphate which was linked to pantetheine 4′-phosphate (**28**). The *R* configuration was unambiguously assigned in 1970 by chemical correlation of (−)-pantolactone with (*S*)-(+)-ethyl pinacolyl ether [1059].

In body cells, the biosynthesis of coenzyme A (**23**) from pantothenic acid (**1**) proceeds via five intermediate steps [1060].

By using high performance liquid chromatography (HPLC), coenzyme A and its precursors can now be separated and quantitatively determined on a picomole scale [1061].

Figure 20. Intermediary metabolism

Pantetheine (**25**) was discovered as a growth promoting substance in lactic acid bacteria and was thus named Lactobacillus bulgariens factor (LBF) [1062]. Chemical synthesis was first achieved by the reaction of methyl (*R*)-pantothenate with cysteamine (**24**) [1063]. Later, higher-yield processes were developed which start with pantothenic acid nitrile (**29**) or calcium pantothenate [1064]. Analogously, the corresponding disulfide, pantethine (**30**), is obtainable from cystamine (**31**) and has interesting pharmaceutical properties [1064].

11.8. Deficiency Symptoms, Requirement, and Application

Spontaneous pronounced deficiency symptoms in humans are unlikely because of the ubiquitous occurrence of pantothenic acid. Clear deficiency symptoms appear in humans only after application of the strong pantothenic acid antagonist ω-methylpantothenic acid. A deficiency of pantothenic acid can be manifested as follows:

1) Impaired adrenal function (insufficiency symptoms), deficiency symptoms in the nervous system (peripheral perception disor-

ders, coordination problems, degeneration of the central/peripheral nerve tracts) [1065]
2) Damage to the skin (dermatitis) and to the hair and nails
3) Gastrointestinal disorders (nausea, vomiting, motility, disturbances) [1066]
4) Impaired reproduction
5) Retardation of growth or loss of weight
6) Degeneration of the liver cells (fat infiltration)
7) Inhibition of immune resistance/antibody formation (increased susceptibility to infection, e.g., infections of the upper respiratory tract)
8) Burning feet syndrome in undernourished persons [1067]

A balanced mixed diet of 10 000 kJ contains ca. 10 mg of pantothenic acid. In Germany, the average daily intake of pantothenic acid is ca. 5 mg/d [1068]. The German Society for Nutrition (1991) set the daily requirement for adults at 6 mg. The Food and Drug Administration in the United States stipulates a daily dose of 4 – 7 mg of pantothenic acid (1989). Symptoms due to large doses of pantothenic acid or panthenol are not known. Extremely high doses are tolerated without side effects, so that pantothenic acid is designated as atoxic.

Apart from the application in acute (*R*)-pantothenic acid deficiency and in preventive treatment against such a vitamin deficiency (e.g., multivitamin preparations), favorable effects in the local treatment of wounds have been reported in the literature.

Calcium (*R*)-pantothenate is preferably used in solid drug forms. The hygroscopicity of the compound must be taken into account. It is also suitable for direct tabletting. In liquid and semisolid forms – especially in combination with other vitamins – (*R*)-panthenol (provitamin B_5) is preferred to calcium (*R*)-pantothenate for reasons of stability. In the topical application of (*R*)-panthenol, a suitable form of this substance (e.g., 5 g/100 g of ointment or solution) is applied to or sprayed on the affected areas once or several times a day.

Calcium (*R*)-pantothenate is added to various foods to prevent pantothenic acid deficiency due to false nutrition or malnutrition or for certain nutritional requirements (baby food; athletes' products; low-calorie, reduced-calorie, and vitamin-rich foods).

(*R*)-Pantothenic acid improves the pigmentation and growth of hair and prevents skin damage. As a result of its higher stability and easier applicability, (*R*)-panthenol is usually preferred to calcium (*R*)-pantothenate, e.g., in hair-care products, sunscreens, shaving lotions, and baby care products.

Pantothenic acid deficiency occurs more often in working animals. The symptoms vary in individual animal species. Apart from a poor general condition, deficiency is characterized by low utilization of fodder, retardation or even arrest of growth, diverse impairments of the skin, mucous membranes, nervous system, blood, digestive tract, reproductory system, and of the adrenals [1069]. In addition, severe pathological changes can occur, including convulsions and paralytic symptoms, especially in the pig [1070], and a higher sensitivity to stress. In the hen, the egg yield is reduced and the brooding results are unsatisfactory [1071]. In severe cases, dermatitis, decolorization and loss of feathers, incrustations of the beak and around the eyes, as well as degeneration of the myelinated nerves occur [1072]. Pantothenic acid is also a vitamin for insects [1073] and acts as a growth substance in plants [1074].

Native pantothenic acid in feedstuffs usually does not cover requirements. Therefore, the composition of the total feed plays an important role. With modern feeding processes and performance demands, pigs and poultry are dependent on supplementation of the feed with pantothenic acid. In the case of ruminants with fully formed rumena, according to present knowledge, the addition of pantothenic acid is not required if the total feed is suited to ruminants. The microbial synthesis of pantothenic acid in these animals is sufficient. However, in calves fed on the basis of milk surrogates, the supply of pantothenic acid from the feedstuff is not adequate. Therefore, appropriate pantothenic acid additives are necessary. Since mixed feed contains on average 6 ppm of pantothenic acid, addition of ca. 50 % of the total requirement is recommended as a safety margin [1076].

Recommended doses in milligrams per kilogram of solo feed are [1075]:

Laying hens	8
Fattening turkeys	15
Porkers	8
Calves	20
Breeding and show horses	60

11.9. Analysis

For calcium (*R*)-pantothenate, the following methods are stipulated in the pharmacopeias (Pharm. Eur. II, US XXII): complexometric determination of calcium, determination of nitrogen by the Kjeldahl method, and measurement of optical rotation.

Furthermore, a 5 % aqueous solution must be clearly water soluble and have a pH value in the range of 6.8 – 8.

As a result of their low sensitivity, chemical detection methods can be applied only to simple mixtures (e.g., multivitamin preparations) [1077]. These analytical techniques include chromatographic preliminary purification (ion exchanger) and hydrolytic cleavage of the active agent, the pantolactone and β-alanine liberated being detected spectrophotometrically [1078], titrimetrically [1079], or colorimetrically (color reaction with ninhydrin or 1,2-naphthoquinone-4-sulfonic acid) [1080].

Pantolactone forms a purple-red hydroxamate with hydroxylamine in alkaline solution in the presence of Fe(III) [1081] and a yellow-green complex with naphthalenediol in sulfuric acid [1079].

The enantiomeric purity of (*R*)-pantolactone can be determined from its specific optical rotation and, more accurately, by gas chromatography on columns with a chiral stationary phase [1082].

As a component of pharmaceutical preparations, (*R*)-panthenol is detected by thin layer chromatographic separation [1083] or directly by ion-pair chromatograpy [1084]. Determination of optical purity can be achieved by gas chromatography after derivatization [1085].

For the determination of pantothenic acid in complex substrates (e.g., in foods and feeds and in tissues and body fluids), microbiological test systems give reliable results. The test organism used is usually *Lactobacillus plantarum* (ATCC 8014) [1086]. Pantothenic acid present in the form of coenzyme A must first be enzymatically released. Combinations of alkaline phosphatase with liver enzymes that cleave pantetheine to pantothenic acid and cysteamine are generally used [1087, 1077].

(*R*)-Panthenol can be determined microbiologically by its growth-inhibiting effect on *Leuconostoc mesenteroides* (ATCC 8042 P-60) [1088]. More recently, immunoassays have been used for the determination of pantothenic acid in blood and tissues. Both the RIA method (radioimmunoassay) [1089] and the ELISA method (enzyme linked immunosorbent assay) [1090] yield results comparable to microbiological tests.

The curative chick growth test [1091] is a biological determination method for free and bound pantothenic acid and for (*R*)-panthenol.

11.10. Economic Aspects

Pantothenic acid is supplied almost exclusively in the form of the calcium salt. The world market volume in 1993 was ca. 6000 t/a. The most important producers are: Hoffmann-La Roche (Scotland), Daiichi (Japan), and BASF (Germany) for calcium (*R*)-pantothenate; Alps (Japan), Terapia (Rumania) and Polfa (Poland) product is also supplied by other smaller producers for the feed sector [1076]. World market prices in 1993 were: calcium (*R*)-pantothenate ca. € 18/kg, calcium (*R,S*)-pantothenate ca. € 7 – 8/kg.

About 80 % of the calcium (*R*)-pantothenate is used in animal feeds and the rest in the food and pharmaceutical sectors.

World annual production of (*R*)-panthenol is ca. 1000 t with a price of ca. DM 43 – 45/kg in 1993. The most important producers of (*R*)-panthenol are Hoffmann-La Roche, Daiichi, and BASF. This product has found diverse applications in the pharmaceutical and cosmetic sectors, especially in the treatment of wounds and for skin- and hair-care products [1092, 1093].

12. Biotin

12.1. Introduction

Biotin [*58-85-5*], 2,3,3a,4,6,6a-hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazole-4-pentanoic

(1) Biotin	X = S	$n = 2$	$z = 2$	Y = COOH
(2) Biocytin	X = S	$n = 2$	$z = 2$	Y = $CONH(CH_2)_4CH(NH_2)COOH$
(3) Dethiobiotin	X = 2H	$n = 2$	$z = 2$	Y = COOH
(4) Selenobiotin	X = Se	$n = 2$	$z = 2$	Y = COOH
(5) Biotin sulfoxide	X = SO_2	$n = 2$	$z = 2$	Y = COOH
(6) Oxybiotin	X = O	$n = 2$	$z = 2$	Y = COOH
(7) Biotinol	X = S	$n = 2$	$z = 2$	Y = OH
(8) Norbiotin	X = S	$n = 1$	$z = 2$	Y = COOH
(9) Homobiotin	X = S	$n = 3$	$z = 2$	Y = COOH
(10) α-Dehydrobiotin	X = S	$n = 2$	$z = 1$	Y = COOH
(11) Biotin sulfone	X = SO	$n = 2$	$z = 2$	Y = COOH

acid, has three asymmetric centers and can occur in eight stereoisomeric forms. However, only the isomer with the configuration (3a*S*,4*S*,6a*R*), D-(+)-biotin (**1**), has full biological activity as vitamin H. Some important derivatives of biotin are presented in Formulas **1** – **11** above.

12.2. History

Biotin was first isolated in 1935. In addition to mesoinositol (Bios I) [*87-89-8*] and pantothenic acid (Bios IIA) [*79-83-4*], a factor Bios IIB was separated from a mixture of substances [1100] known as growth factor Bios for microorganisms [1101]. Bios IIB was named biotin. A year later crystalline biotin methyl ester [*608-16-2*] was isolated from dried egg yolk [1102]. It was verified [1103] shortly afterwards that biotin was identical to both vitamin H [1104], a protective factor against egg white injury caused by one-sided consumption of large amounts of raw eggs [1105], and coenzyme R [1106], a factor necessary for the growth and respiration of the bacteria of the root tubercles of leguminous plants.

In 1942, the structure of biotin was established by degradation reactions [1107, 1108]. This was followed by the first, albeit stereochemically nonspecific, total synthesis of biotin [1109]. The first stereospecific synthesis of pure enantiomers and diastereoisomers of biotin was achieved in 1949 [1110–1112].

12.3. Physical and Chemical Properties

D-(+)-Biotin (**1**) $C_{10}H_{16}N_2O_3S$, M_r 244.31, is readily soluble in dilute alkalis, hot water, and 95 % ethanol, slightly soluble in cold water and dilute acids, and almost insoluble in organic solvents. It crystallizes from water as long thin needles, *mp* 230 – 232 °C (decomp.), $[\alpha]_D^{22}$ +92.0° ($c = 1$, 0.4 % NaOH) [1113]. Crystalline biotin has an orthorhombic structure [1114]. The thiophane ring has the same conformation in solution and in the solid state. The sulfur lies above the plane of the ring and the valeric acid side chain occupies a quasi-equatorial position [1115]. Crystalline biotin is stable in air, thermally stable, and resistant to sunlight. It is, however, instable when exposed to UV light, oxidizing agents, and strong acids and strong bases.

With avidin [*1405-69-2*], biotin forms a molecular compound, in the ratio of 4 : 1, having one of the most stable noncovalent bonds known [1116, 1117]. Avidin, a glycoprotein contained in raw egg white, has a molar mass of ca. 70 000. This molecular compound can be cleaved neither enzymatically (peptidases) nor by acids, but only by the denaturation of avidin by radiation or by heating at 100°C for a longer period of time. Biotin forms similarly strong complexes with the related proteins streptavidin [*9013-20-1*] and stravidin [*97276-57-8*] which are formed in the fungi *Streptomyces* and *Saccharomyces* [1118].

12.4. Occurrence

Biotin occurs in varying amounts, either in the free state or bound to proteins, in most foodstuffs. The richest natural sources of biotin are yeasts [1119], lower fungi [1120], and microorganisms [1121]. Microorganisms excrete such large amounts of biotin into the surrounding

medium that most animals can cover their biotin requirement through microbiological synthesis within the intestinal tract. In humans, the fecal excretion of biotin exceeds external intake, indicating endogenous biosynthesis by intestinal flora. In plants, biosynthesis of biotin is localized in the leaves; therefore, cultivated green cells of *Lavendula vera* have an especially high biotin content [1122]. Since biotin can also be resorbed from the soil through the roots, it is distributed throughout the entire plant. Some types of phytoplankton are capable of biosynthesizing biotin as well, e.g., *Skeletonema costatum, Stephanopyxis turris* or *Gonyaulax polyedra*.

Fresh cow's milk, with a biotin content of 2.0 – 3.5 µg/mL, is one of the most important exogenous natural sources for the biotin requirement of humans [1123]. Depending on the stage of lactation, breast milk also contains varying amounts of biotin (0.06 – 0.29 µg/mL in the colostrum stage and 0.81 – 1.30 µg/mL during the nursing period) [1124]. In contrast to meat, beef liver (up to 100 µg/100 g) and kidney have an especially high biotin content. Among human foodstuffs, other fairly good sources of biotin are eggs, some vegetables (e.g., soya with 60 µg/100 g or lentils), cereals (e.g., rolled oats with 20 µg/100 g), and nuts [1123]. In smaller amounts (0.1 – 5.0 µg/100 g), biotin is a ubiquitous component of all other foodstuffs. Remarkably, the biotin content of cheese increases fourfold during maturation due to bacterial synthesis.

In some foodstuffs, such as meat or plant shoots, biotin is present in the bound form as biocytin (ε-*N*-biotinyllysine) [*576-19-2*]. Since the body can resorb only free biotin, this amide is quantitatively hydrolyzed to biotin and L-lysine [*56-87-1*] in the gastrointestinal tract by the enzyme biotinidase [1125, 1126]. However, humans utilize only ca. 50 % of ingested biotin; the rest is excreted in the feces. Accordingly, sedimentation sludge with 50 – 70 µg of biotin/100 g of solids represents a further, albeit not directly exploitable, source of biotin.

12.5. Biosynthesis

The biosynthesis of biotin in individual microorganisms is now well studied and described in detail in the literature [1127, 1128]. Although there is no uniform precursor, biosynthesis usually starts with pimelic acid [*111-16-0*] and acetyl coenzyme A, which are converted by pimelyl CoA synthetase to pimelyl coenzyme A, which undergoes decarboxylation with L-alanine [*56-41-7*] to give 7-oxo-8-aminopelargonic acid [*4707-58-8*]. This reaction is catalyzed by the pyridoxal phosphate dependent enzyme 7-oxo-8-aminopelargonic acid synthetase. Subsequently, 7,8-diaminopelargonic acid aminotransferase transfers the amino group from *S*-adenosylmethionine [*29908-03-0*] to give 7,8-diaminopelargonic acid [*21738-21-6*]. This compound then undergoes ring closure with dethiobiotin synthetase and bicarbonate, ATP, and Mg^{2+} to give dethiobiotin [*533-48-2*]. Finally, sulfur is incorporated into biotin with the aid of thiobiotin synthetase (Scheme 26) [1132].

In this unusual reaction, the sulfur presumably comes from L-cysteine [*56-89-3*] [1129] and is incorporated at the prochiral C-4 of dethiobiotin with retention of configuration, eliminating the pro-4*S* hydrogen [1130]. Accordingly, cystine, pimelic acid, and dethiobiotin promote biosynthesis in biotin culture media. However, biotin itself causes negative feedback inhibition of biosynthesis, probably by repressing formation of most of the enzymes required for synthesis [1131].

Other precursors include glutaric acid [*110-94-1*] and pelargonic acid [*112-05-0*], the latter being the precursor for biosynthesis in a strain of *Pseudomonas* [1133].

For conversion to the biologically active biotin enzyme, biotin is subsequently activated by adenosine triphosphate with the formation of biotin adenosinylate [*4130-20-5*]. This substance reacts with the ε-amino group of an L-lysine residue of apoenzymes to give the active cofactor biocytin.

12.6. Function as Prosthetic Group

Enzymes which contain biotin as cosubstrate or coenzyme are classified as carboxylases (carboxylation via hydrogencarbonate), transcarboxylases (transfer of carboxyl function), and decarboxylases (Na transport with decarboxylation), depending on their metabolic function. However, only carboxylases play a role in higher organisms [1134, 1135]. All three classes have in

Scheme 26. Biosynthesis of biotin (enzymes and *E. coli* genes)

common a two-step mechanism. The carboxyl group is first transferred to the biotin enzyme, and then reacts further in a substrate-specific manner. In this process, the carboxylases must be activated with ATP, while the trans- and decarboxylases are independent of ATP [1136]:

$$\text{E-Biotin} + \text{ATP} + \text{HCO}_3^- \rightleftharpoons \text{E-Biotin-CO}_2^- + \text{ADP} + \text{P}$$

$$\text{E-Biotin-CO}_2^- + \text{R-H} \rightleftharpoons \text{E-Biotin} + \text{R-CO}_2^-$$

$$\sum: \text{R-H} + \text{ATP} + \text{HCO}_3^- \rightleftharpoons \text{RCO}_2^- + \text{ADP} + \text{P}$$

In addition, metal cations such as Mg^{2+}, K^+ or Mn^{2+} are required for enzyme activity. However, they play a more structural than participative role. As expected, avidin inhibits all the biotin-dependent steps of the carboxylases.

Some of the important biotin-dependent carboxylases are listed in Table 34. A series of review articles are available for detailed information on biotin enzymes [1134, 1135].

Table 34. Biotin dependent enzymes (carboxylases)

Enzyme	Catalyzed reaction	Role in metabolism
Acetyl CoA carboxylase	acetyl CoA → malonyl CoA	fatty acid biosynthesis
Pyruvate carboxylase	pyruvate → oxalacetate	gluconeogenesis, lipogenesis
Propionyl CoA carboxylase	propionyl CoA → methylmalonyl CoA	propionate metabolism
3-Methylcrotonyl CoA carbo- xylase	3-methylcrotonyl CoA → 3-methylglutaconyl CoA	leucine catabolism
Geranyl CoA carboxylase	Geranyl CoA → carboxygeranyl CoA	catabolism of isoprenoid compounds
Urea carboxylase	urea → *N*-carboxyurea	metabolization of urea in yeasts to a utilizable form

12.7. Isolation and Production

Isolation from Natural Sources. Biotin was first isolated from the natural sources egg yolk [1102], ox liver [1137], and milk [1138]. The extracts are subjected to an elaborate purification procedure, and crude biotin is finally precipitated with phosphotungstic acid [*1343-93-7*]. After conversion to the methyl ester, purification is carried out by high-vacuum sublimation or molecular distillation. However, the amounts isolated are out of all proportion to the effort required. Genetically modified strains of *E. coli* and *Bacillus sphaericus* have proved to be a richer source of natural biotin [1128]. Concentrations of up to 230 mg/L have already been obtained in fermenter charges [1139].

However, all the biotin used in the animal feed or pharmaceutical industry is still produced synthetically and corresponds to the natural product in all respects.

Industrial Synthesis [1099]. The first nonstereospecific total synthesis of biotin started with L-cysteine and involved the formation of the thiophane ring, followed by cyclization of the imidazolone segment. It produced all eight isomers of biotin [1109]. Following this proof of structure, GOLDBERG and STERNBACH were able in their synthesis to reduce the number of isomers to one separable pair of diastereomers (3a*S*,4*S*,6a*R*-(+)- and 3a*R*,4*S*,6a*S*-(−)-biotin) [1110–1112]. Their process provided the foundation for the modified synthesis of GERECKE [1140], which is the basis for almost all industrial syntheses of biotin. This improved process has the advantage of the economically more favorable separation and recycling of the biologically inactive L-(−) isomer to an earlier stage in the synthesis (Scheme 27).

More recent efforts to optimize this synthesis include shifting the isomeric ratio to favor (+)-biotin by asymmetric induction with optically active amines [1141] or alcohols [1142], recycling and isomerization of (−)-biotin [1143], or a simpler introduction of the exocyclic valeric acid group by means of the Wittig reaction [1144] or by using ortho esters [1145].

The recent literature contains numerous efforts to find new methods for the synthesis of racemic and diastereoisomerically pure biotin (Table 35).

In the latter case, efforts are made to transfer asymmetric centers from natural chiral substrates, such as sugars or amino acids, to the target molecule. Until now, however, none of these syntheses can compete with the modified Gerecke process in industrial application.

In the past years, rapid progress has been made in the biosynthetic preparation of biotin via genetically modified bacterial strains (see above). To seriously compete with the stereospecific total chemical synthesis, biotin concentrations of at least 1 g/L of fermentation solution must be attained. Therefore, the current biosyntheses which give concentrations of not more than 230 mg/L are still not feasible.

12.8. Metabolism and Importance for the Organism

Biotin ingested with food is present in the body either in the free state or protein-bound in the form of biocytin. The latter is cleaved into biotin and ε-lysine by the enzyme biotinidase, which is found in most mammals [1168]. The uptake of free biotin in the intestinal tract is not yet well understood. However, it appears that an active, carrier-mediated transport mechanism plays a role at low biotin concentrations, and a passive diffusion mechanism at high biotin concentrations [1169, 1170]. The intracellular accumulation of biotin in various bacterial strains also proceeds in an energy-dependent protein carrier process [1171].

In the plasma, 80 % of the biotin present is protein bound [1172]. Transport probably occurs via biotinidase and is not linked to any energy source [1173]. Biotin cannot be degraded in mammalian metabolism. The only reaction that has been observed is oxidation to biotin sulfoxide [*3376-83-8*] and tetrabisnorbiotin in the mitochondria after activation of the carboxyl group [1174]. Both metabolites as well as biotin are excreted in the urine and feces. The total excretion of biotin usually exceeds the intake [1175].

Various bacterial strains and molds are capable of metabolizing biotin completely. Thus, strains of *Pseudomonas* use biotin as the sole source of C, N, and S. Degradation proceeds via stepwise β-oxidative decomposition of the side chain and the thiophane ring. Finally, the imidazolidine ring is metabolized to urea [1128].

As a coenzyme (see above) for a series of important metabolic functions (e.g., CO_2 fixation and transfer) biotin is of essential importance for both micro- and macroorganisms. Therefore, several metabolic functions are simultaneously disturbed in biotin deficiency.

12.9. Deficiency Symptoms, Requirement, and Application

Biotin deficiency can be produced in humans and animals by diets low in this vitamin, consumption of large amounts of raw egg white, or by the administration of sulfonamides, which act as antivitamins by competitive enzyme inhibition [1175]. Manifestations of biotin deficiency in mammals include alopecia, pruritus, dermatitis, central nervous disorders, formation of crusts and rhagades, and hypercholesterinemia [1176].

12.9.1. Symptoms and Therapy in Humans

Biotin deficiency can be produced in humans by a one-sided diet of raw eggs [1177], alcohol abuse [1178], side effects of some drugs (e.g., sulfonamides or antiepileptics) [1179], inborn genetic defects (absence of biotin enzymes) [1180], or by incomplete parenteral nutrition [1181]. In babies, biotin deficiency can also occur after an excessively long nursing period (>4 months) due to the sinking biotin levels in breast milk [1182].

In 1942, biotin avitaminosis [1183] was first described by Sydensticker. He fed four adult test persons with a one-sided diet rich in egg white. The first typical symptoms, such as depresion, muscular pain, and irritability, appeared after 3 – 4 weeks. Longer term biotin deficiency leads to desquamative, maculosquamous, and seborrheic dermatitis; sleepiness; local paraesthesiae, anorexia; alopecia; ataxia; and glossitis. The normal blood values with regard to hematocrit, cholesterol, and bile pigments are altered; the excretion of biotin in the urine decreases from 30 – 50 to 3 – 7 µg/d.

Is is also possible that sudden infant death syndrome (SIDS) is also due to vitamin deficiency [1184], as suggested by the low hepatic biotin level found in the dead babies.

All the symptoms, which are biochemically caused by a disturbance in glucogenesis and potassium deficiency in the muscles, can be reversed in a very short time by oral or parenteral administration of ca. 150 µg/d of biotin. Biokinetic studies on the turnover of biotin and validated deficiency experiments are not yet available. Hence, all the known biotin requirement values are estimates. The recommendation made by the DGE (German Society for Nutrition) is 30 – 100 µg of biotin per day for adults.

12.9.2. Symptoms and Therapy in Animals

Symptoms of biotin avitaminosis in higher organisms were first observed in rats given a diet rich in egg white [1104]. After 2 – 4 weeks, the rats suffered from egg white injury, which exhibits the typical biotin deficiency symptoms. It starts with progressive dermatitis, especially of the genitals, spreading to the neck and muzzle. In the further course of the syndrome, the dermatitis becomes pronounced and resembles Leiner's disease. This is followed by alopecia, pruritus, edema, and a characteristic spastic gait (kangaroo posture). A low fat content in the diet increases the symptoms, whereas administration of ascorbic acid (vitamin C) slows down the syndrome [1185].

Before the outer signs become significant, there is a marked decrease in the activity of the biotin-dependent enzymes pyruvate and acetyl CoA carboxylase. The enzymes are transformed into vitamin-free apoenzymes, which, however, can be reactivated by addition of biotin in an ATP-dependent process [1186]. Apart from potassium deficiency in the striated neuromuscles, a further pathological symptom is the increase in the C_{16} fatty acid content and the cholesterol level in the tissue [1187].

As with other higher organisms, all the symptoms can be completely reversed within 2 – 4 weeks by the external supply of 3 – 8 µg of biotin per 100 g of animal food.

Most of these avitaminosis symptoms, such as dermatitis, loss of hair and feathers, depigmentation, encrustations of the eye lids, growth inhibition, and weight loss, are also found in other animals, including fish, hens, pigs, dogs, and monkeys [1175, 1188]. In the case of chicks, marginal deficiency symptoms also include per-

osis as well as fatty liver and kidney syndrome. The latter results in a very high mortality of the young animals due to disturbed hepatic glucogenesis via pyruvate carboxylase. The symptoms are similar to those of SIDS (see above) [1189].

12.10. Biotin Analogs

Of the 8 possible stereoisomers of biotin, only the D-(+) form (**1**) has biological activity. Its naturally occurring form, having the same activity, is biocytin, biotin ε-lysine (**2**). Biotin can be liberated from this compound by acid hydrolysis or enzymatically with biotinidase [1190].

Some analogs also show biological effects, but only in the configuration corresponding to the D-(+) form. Dethiobiotin (**3**), which can readily be made by reduction of biotin, can fully substitute for biotin as a growth factor in some microbial substrates, such as *E. coli* or *Bacillus sphaericus* [1191]. Therefore, it is certain that dethiobiotin is a precursor of biotin [1130]. After incorporation into acetyl CoA carboxylase, selenobiotin [*57956-29-3*] (**4**) exhibits coenzymatic properties comparable to those of biotin [1192]. Selenobiotin can be made synthetically or isolated microbially from *Phycomyces blakesleanus*. Like biotin sulfoxide (**5**), it can totally replace biotin in lower organisms. In the case of higher organisms, oxybiotin [*14474-91-0*] (**6**) and biotinol [*53906-36-8*] (**7**) are the only analogs capable of replacing biotin in the diet without the appearance of deficiency symptoms. Vitamin deficiency symptoms in rats are also modified by these analogs, but to a limited extent.

Biotin derivatives that are modified in the side chain, such as norbiotin [*669-72-7*] (**8**), homobiotin [*1784-22-1*] (**9**) or α-dehydrobiotin [*10118-85-1*] (**10**) are generally active antagonists for microorganisms such as *Lactobacillus casei* or *Saccharomyces cerevisiae*. α-Dehydrobiotin is one of the strongest antagonists known until now. When incubated with apocarboxylases, it irreversibly prevents the binding of biotin to the enzyme [1193]. Biotin sulfone [*40720-05-6*] (**11**) has a minor resorption-inhibiting effect. The most effective biotin antagonists are the glycoprotein avidin found in raw egg white and the proteins stravidin and streptavidin produced by microorganisms [1194].

12.11. Analysis and Standardization [1098]

For the determination of biotin concentrations in serum, bioassays using biotin-deficient animals were mainly employed in the past. The disadvantages of this method are the low accuracy and high time consumption [1195].

Highly specific biotin determinations are possible with microbiological and radioisotope dilution assays. Microbiological determination is based on the measurement of the increase in the amount of the corresponding substrates (see Table 36) after administration of a sample of unknown biotin concentration compared with several standard solutions. The biotin contained in the sample must be converted to a bioavailable form by treatment with acid or papain [*9001-73-4*], and unsaturated fatty acids must be removed because they interfere with the assay. After inoculation and incubation, the determination of the biotin concentration (detection limit 0.1 ng) is carried out by turbidimetry or titrimetry. The disadvantage of this process is that diverse biotin analogs are also included, depending on the microbe [1196].

More recent methods, including the radioisotope assay, make use of biotin – avidin technology. Identical samples of radioactively labelled avidin are treated in parallel with the unknown sample and standard biotin solutions. Subsequently, the samples are fixed via immobilized biotin. The concentration – amounts as low as 0.1 ng can be determined [1199] – is directly obtained from the count rate [1200]. Apart from labelling by means of doping, fluorescence [1201] and chemiluminescence measurements [1202] have also been used for detection.

In general, chemicophysical methods are employed for the purification and definition of purity. The purification is conveniently conducted by ion exchange [1203, 1204], paper, thin-layer, or liquid chromatography [1098]. Detection is carried out refractometrically or by reaction with color reagents. The sensitivity of the latter methods, which detect either visually or by UV/fluorescence measurements, varies between 0.3 and 50 ng [1205]. Finally, purity testing can

be completed by using NMR, LC/GC – MS, and polarography.

There is no international standard for biotin.

12.12. Uses and Economic Aspects

The annual production of 25 t of biotin is largely used in the animal feed, pharmaceutical, and food industries. To a minor extent, it is also used together with avidin for analytical purposes in immunoassays, as an additive in nutrient media for microbial substrates, and in the cosmetic industry.

In the large-scale husbandry of domestic animals, the use of biotin as a feed additive is based on the prevention of the readily occurring biotin deficiency symptoms caused by the lack of this coenzyme, which is essential in a series of important metabolic functions. In pharmacy, biotin is used – in the form of multivitamin tablets, dragees, capsules, or syrup – exclusively to prevent vitamin deficiency symptoms, which can occur, e.g., after operations, during pregnancy and lactation, and in growth phases.

In immunology, diagnostics, and biochemical research, the use of biotin – avidin technology [1096, 1206] has undergone rapid development in the last few years. The method is based on two principles. First, biotin can easily be functionalized via its carboxyl group and, secondly, the bicyclic unit with which binding to avidin occurs is spatially far removed due to a spacer of four methylene groups. Avidin can also be activated with suitable substrates. Thus, two otherwise chemically inert substrates can be joined together by means of the biotin – avidin complex. In tumor therapy, for instance, antitumor antibodies are biotinylated and the tumor cells are treated with these immunoglobulins. Subsequently, the damaged cells are incubated with an avidin – cytostatic agent complex. The resulting formation of the avidin – biotin complex results in the drug being brought directly to the cancer cell without interfering with healthy cells [1207, 1208].

The application of biotin – avidin technology in numerous immunoassays [1209], in the separation and purification of immunoglobulins from sera [1210] (see Fig. 21), and in the detection of DNA or RNA fragments in hybridization experiments [1211] is based on the same principles.

These uses and pharmaceutical and food technological purposes, however, require only 5 – 10 % of the annual production of 25 t of biotin (100 %). The majority is employed in the animal feed industry.

The main producers of biotin are Hoffmann-La Roche (Switzerland), Tanabe (Japan), Sumitomo (Japan), Merck (Germany), Il Sung (Korea), Lonza (United States), and, for feed-quality only, BASF (Germany).

The world market price of 1 g of 100 % pure D-(+)-biotin is ca. 5 €(1995).

A) Binding of biotinylated protein (antibody) to immobilized avidin; B) Addition of specific antigen; C) Binding of immobilized antibody – antigen; D) Elution of biotinylated antibody – antigen complex via displacement of avidin with free biotin

12.13. Tolerance and Environmental Protection

Even after the administration of large amounts of biotin, no acute toxicity in humans or animals has been observed [1212]. Thus, doses of up to 10 mg of biotin per 100 g of body weight showed no side effects in rats. A six-month therapeutic treatment of humans with 10 mg/d resulted in no harmful effects on body functions. Injections of 1 mg of biotin/kg of body weight in pregnant rats, however, caused resorption of the fetus and placenta and disturbances of estrogen formation [1213].

Biotin is considered environmentally harmless and is subject to no special regulations with regard to storage and transport. No explosion limits exist for biotin. Water, carbon dioxide, foam, or powder can be used as extinguishing agents in the case of fire. As a result of its acidic carboxyl function, classification as a weakly water endangering substance is being considered. Normal personal and hygienic measures (protective glasses, washing of hands) should be taken when working with biotin. Ecological problems are not to be expected if biotin is properly handled and used [1214].

13. Folic Acid

13.1. Introduction

Folates are a group of biologically active compounds which are structurally derived from

pteroylglutamic acid or folic acid (**1**). The chemical structure can be divided into the three substructures 6-methylpterin, *p*-aminobenzoic acid and L-glutamic acid. The Chemical Abstracts name is *N*-[4-[[(2-amino-1,4-dihydro-4-oxo-6-pteridinyl)methyl]amino]benzoyl]-L-glutamic acid.

Folic acid (**1**)
Pteroylglutamic acid (PteGlu)

Table 37. H_4folate cofactors

R^1	R^2	Nomenclature *	Configuration of natural stereoisomer
2 H	H	tetrahydrofolic acid (H_4folate)	(6*S*,α*S*)
3 CH_3	H	5-methyltetrahydrofolic acid (5-CH_3-H_4folate)	(6*S*,α*S*)
4 $-CH_2-$		5,10-methylenetetrahydrofolic acid (5,10-CH_2-H_4folate)	(6*R*,α*S*)
5 HC=O	H	5-formyltetrahydrofolic acid (5-HCO-H_4folate)	(6*S*,α*S*)
6 H	HC=O	10-formyltetrahydrofolic acid (10-HCO-H_4folate)	(6*R*,α*S*)
7 HC=NH	H	5-formiminotetrahydrofolic acid (5-NHCH-H_4folate)	(6*S*,α*S*)
8 $-\overset{+}{C}H-$		5,10-methenyltetrahydrofolic acid (5,10-CH^+-H_4folate)	(6*R*,α*S*)

* [1215].

Enzymatic reduction of folic acid leads to 7,8-dihydrofolic acid (H_2folate), a key substance in biosynthesis. Further reduction, catalyzed by the enzyme dihydrofolic acid reductase, provides (6*S*)-5,6,7,8-tetrahydrofolic acid (H_4folate) (**2**). This is the parent compound of the folates **3**–**8** possessing at N-5 and/or N-10 an additional C_1 substituent (Table 37). These substances and the corresponding polyglutamates are essential coenzymes for the transfer of C_1 units of different oxidation levels. In cofactor **8** with a methenyl group ($-CH^+-$) bridging positions 5 and 10, a positive charge is associated with the substructure $[N(5)-CH-N(10)]^+$. All natural folates have the same absolute configuration at position 6 as (6*S*)-tetrahydrofolic acid (**2**).

In contrast, chemical reduction of folic acid gives (6*RS*)-5,6,7,8-tetrahydrofolic acid, a diastereomeric mixture of (6*S*,α*S*)- and (6*R*,α*S*)-H_4folate. Nomenclature and symbols for folic acid and related compounds are subject of recommendations published by the IUPAC–IUB Joint Commission on Biochemical Nomenclature (1986) [1215].

In living cells folates are predominantly stored as polyglutamates in which the second and subsequent molecules of L-glutamate are each linked by amide bonds to the γ-carboxyl of the preceding glutamate unit.

Pteroylpolyglutamic acid, $PteGlu_n$ $n \geq 1$

13.2. Historical Notes

In the 1930s, a dietary factor in yeast extracts and crude liver was found to cure megaloblastic anemia in pregnant women [1216]. Experimentally, this disorder could also be induced in monkeys and cured by antianemic factor (vitamin M). Two bioassay procedures, the microbiological growth assay and the antianemic factor assay in chickens (vitamin B_c), were developed and used to follow the isolation and purification of folates [1217–1219]. A close relationship between the yeast growth factor and the antianemic factor was soon established, but it became evident that the yeast growth factor and vitamin B_c were different entities. A crystalline preparation of a high molecular mass derivative of folate was

isolated [1220] and later shown to be a peptide [1221]. The unequivocal elucidation of the structure of pteroylglutamic acid (**1**) was achieved in 1946 by ANGIER et al. [1222]. The discovery of folates and developments during the following decade are reviewed in [1223].

13.3. Properties

This chapter describes some properties of selected folates [1224–1227]. UV data are given as λ_{max} (ε) in nanometers.

Folic acid (**1**), pteroylglutamic acid, PteGlu [*59-30-3*], $C_{19}H_{19}N_7O_6$, M_r 441.41; yellow thin platelets, no *mp*, chars above 250°C; UV (pH 13): 256 nm (30 000), 282 nm (26 000), 365 nm (9800); $[\alpha]_D^{27} = +19.9°$ (0.1 N NaOH). Contains ca. 8 % water which is lost in vacuum at 90°C. Soluble in aqueous alkali metal hydroxides and carbonates and in aqueous mineral acids, less soluble in acetic acid and pyridine, slightly soluble in hot water, very slightly soluble in cold water, insoluble in acetone and chloroform. Stable in crystalline form in the dark at room temperature; unstable in alkaline and acidic solution.

Dihydrofolic acid, 7,8-dihydropteroylglutamic acid, H_2folate [*4033-27-6*], $C_{19}H_{21}N_7O_6$, M_r 443.42; UV (pH 7.2): 282 nm (28 600). Preparation from folic acid by catalytic hydrogenation or sodium dithionite reduction in presence of ascorbic acid [1228]. Highly air sensitive compound.

Tetrahydrofolic acid (**2**), 5,6,7,8-tetrahydropteroylglutamic acid, H_4folate [*135-16-0*], $C_{19}H_{23}N_7O_6$, M_r 445.44; UV (pH 7.85): 296 nm (28 000). Synthesized from folic acid by catalytic hydrogenation in acidic solution or by reduction with sodium cyanoborohydride [1229]. Very sensitive to oxygen. (6*RS*)-H_4folate has $[\alpha]_D^{27} = +14.9°$ (0.1 N NaOH). Natural (6*S*)-H_4folate [*71963-69-4*] has $[\alpha]_D^{27} = -16.9°$ (0.1 N NaOH).

5-Methyltetrahydrofolic acid (**3**), 5-CH_3-H_4-folate [*134-35-0*], $C_{20}H_{25}N_7O_6$, M_r 459.46; UV (pH 7): 290 nm (32 000). Synthesis from H_4-folate by condensation with formaldehyde and reduction of the resulting 5,10-CH_2-H_4-folate with sodium borohydride [1230]. **3** is more stable towards oxygen than H_4folate.

5,10-Methylenetetrahydrofolic acid (**4**), 5,10-CH_2-H_4folate [*3432-99-3*], $C_{20}H_{23}N_7O_6$, M_r 457.45; UV (pH 7.2): 294 nm (32 000). Preparation from H_4folate and formaldehyde. Very sensitive to hydrolysis. Synthesis of the natural (6*R*)-stereoisomer by enzymatic reduction of H_2folate and treatment with formaldehyde [1231]. Coenzyme in thymidylate biosynthesis.

10-Formyltetrahydrofolic acid (**6**), 10-HCO-H_4-folate [*2800-34-2*], $C_{20}H_{23}N_7O_7$, M_r 473.45; UV (pH 7.5): 260 nm (17 000). The unstable compound **6** is prepared by hydrogenation of 10-HCO-folate or by hydrolysis of 5,10-CH^+-H_4folate [1232]. Coenzyme in purine synthesis.

5-Formyltetrahydrofolic acid (**5**), (6*RS*)-5-HCO-H_4folate, folinic acid, leucovorin [*58-05-9*], $C_{20}H_{23}N_7O_7$, M_r 473.45; UV (pH 13): 282 nm (32 600); $[\alpha]_D^{25} = +16.0°$ (H_2O, Ca salt). Most stable of the H_4 folate cofactors. Preparation by hydrolysis of 5,10-CH^+-H_4folate in neutral or alkaline solution or by direct formylation of H_4folate [1233]. (6*S*)-5-HCO-H_4folate, citrovorum factor, *l*-leucovorin [*68538-85-2*]; $[\alpha]_D = -13.3°$ (H_2O). Enzymatic synthesis of the natural (6*S*)-stereoisomer from H_2folate [1234, 1235]. Preferential crystallization of the Ca salt of natural (6*S*)-5-HCO-H_4folate from (6*RS*)-5-HCO-H_4folate in water [1236]. 5-HCO-H_4folate is used in medicine as an antidote to folic acid antagonists such as methotrexate.

5-Formiminotetrahydrofolic acid (**7**), 5-NHCH-H_4folate [*2311-81-1*], $C_{20}H_{24}N_8O_6$, M_r 472.46; UV (pH 7): 285 nm (35 400). Fast hydrolysis in aqueous solution.

5,10-Methenyltetrahydrofolic acid (**8**), 5,10-CH^+-H_4folate, anhydroleucovorin [*65981-89-7*], $C_{20}H_{22}N_7O_6^+$ (cation); UV (pH 1): 352 nm (23 900). Preparation by dehydration of 5-HCO-H_4folate in acidic medium [1235].

13.4. Content in Food and Bioavailability

Folic acid is synthesized de novo by microorganisms and plants; mammals require it in their diet. Folates are present in all food products of animal and plant origin, especially in green-leaved vegetables. Liver has a notably high content. The folate content (in µg/100 g) of some foods is given in the following [1237–1241]:

Lettuce	106 – 200
Spinach	78 – 194
Asparagus	50 – 195
Cabbage	30 – 79
Broccoli	71 – 189
Tomatoes	6 – 73.4
Beans	68 – 100
Apples	3 – 6
Oranges	24 – 37
Bananas	22 – 36
Avocados	30 – 36
Beef	5 – 18
Beef liver	141 – 330
Kidney	63
Chicken	5 – 28
Eggs	65 – 140
Milk	5 – 20.5
Cheese	20 – 66
Fish	4.5 – 15

Most sources list the total folate content [1237–1240], but occasionally a distinction is made between mono- and polyglutamates. To take into account the lower bioavailability of polyglutamates, a folate equivalent can be calculated [1241]. The wide range of folate contents most likely reflects different methods used for determination.

Food processing, storage, and cooking reduce the content of folates considerably [1242–1244]. Different forms of folate vary in stability. In particular, oxidation results in inactive cleavage products. Folates can be stabilized for longer periods in the presence of reducing agents such as ascorbate.

In humans, folic acid is almost completely absorbed under fasting conditions. The absorption of folylpolyglutamates is 50 – 80 % of that of monoglutamates as judged by urinary excretion [1245, 1246]. This percentage may be lowered in the presence of many foods.

13.5. Biosynthesis

Folic acid is synthesized in microorganisms and plants from the precursors guanosine 5′-triphosphate (GTP), *p*-aminobenzoic acid, and L-glutamic acid. The enzymatic steps involved in folate biosynthesis in enteric bacteria have been extensively reviewed by Brown and Williamson [1247, 1248]. The pathway is shown in Figure 22 A. GTP is converted by GTP cyclohydrolase I (EC 3.5.4.16) to 7,8-dihydroneopterin triphosphate. This transformation includes the hydrolysis of the annelated imidazole ring, elimination of the C-8 atom as formate, Amadori rearrangement, and ring closure to the pyrazine ring involving the ribose C-2′ atom. The pyrophosphate group is subsequently hydrolyzed chemically [1249] or by a nonspecific pyrophosphatase so far only described in *E. coli* [1250]. The residual phosphate is removed by an as yet uncharacterized phosphomonoesterase. Hydroxymethyl-7,8-dihydropterin pyrophosphate is then obtained by a retro-aldol reaction with removal of a hydroxyacetaldehyde moiety and subsequent addition of a pyrophosphate group. Condensation of *p*-aminobenzoic acid with hydroxymethyl-7,8-dihydropterin py-rophosphate is carried out by dihydropteroate synthase (E.C. 2.5.1.15) leading to 7,8-dihydropteroate. L-Glutamate is then attached to this intermediate by dihydrofolate synthetase. In some microorganisms, this enzyme also has folylpolyglutamate synthetase activity [1251].

Organization of genes encoding for the folate biosynthetic enzymes varies greatly among bacteria. In *Bacillus subtilis* and *Streptococcus pneumoniae* folate operons were shown to carry six and four biosynthetic genes, respectively [1252, 1253], while in *E. coli* biosynthetic genes are spread along the chromosome. In *B. subtilis*, genes for folate biosynthesis were found at three different locations on the chromosome (Figure 22B). They have been cloned and sequenced [1252, 1254, 1255]. First, the *mtr* operon maps at position 204° and encodes GTP cyclohydrolase I and tryptophan RNA-binding attenuation protein (TRAP) [1254]. Second, the *folC* gene encoding dihydrofolate synthetase maps at position 258° and is not linked to the other genes of folate biosynthesis [1255]. Third, a folic acid biosynthetic operon mapping at po-

Figure 22. Biosynthesis of folic acid
A) Biochemical pathway; B) Genes encoding enzymes of folate biosynthesis in *Bacillus subtilis*

sition 10° encodes for the three subunits of *p*-aminobenzoate synthase, dihydroneopterin aldolase, hydroxymethyl pyrophosphokinase, and dihydropteroate synthase [1252].

Industrial production of folic acid by genetically engineered microorganisms or extraction from natural sources is not yet economically viable.

13.6. Chemical Synthesis

Folic acid (**1**) was first synthesized by condensation of 2,5,6-triamino-4(3*H*)-pyrimidinone (**9**), *p*-aminobenzoyl-L-glutamic acid (**10**), and 2,3-dibromopropanal (**11**) [1222, 1256].

9

10

11

12

13

Later variants of this one-pot process replaced the C_3 component **11** by various other compounds, such as 1,1,3-tribromo-2-propanone [1257], 2,2,3-tribromopropanal [1257], 2,2,3-trichloropropanal (**12**) and 1,1,3-trichloro-2-propanone (**13**) [1258]. Addition of sodium bisulfite to the reaction medium substantially increased the yield of folic acid [1258].

Syntheses of folic acid by stepwise condensation of **9**, **10**, and a C_3 component have also been reported. For example, 2-amino-6-(hydroxymethyl)pteridinone (**14**), prepared by condensation of **9** with 1,3-dihydroxy-2-propanone, was reacted with **10** to give folic acid (**1**) [1259]. In a different two-step synthesis, 2-hydroxymalondialdehyde was condensed with two equivalents of **10**. Subsequent reaction of the resulting diimine with **9** provided folic acid [1260].

Condensation of triaminopyrimidinone (**9**) with unsymmetrical C_3 compounds invariably leads to regioisomeric byproducts substituted in position 7.

14

15a: R = H
15b: R = $COCH_3$

16

6-Formylpterin (**15b**) is another viable intermediate for the synthesis of folic acid. It can be prepared from triaminopyrimidinone (**9**) and 2-bromo-3,3-diethoxypropanal with H_2O_2 as oxidizing agent, followed by acetylation and hydrolysis [1261]. A synthesis of **15a** from the pyrazine derivative **16** has been developed as a route giving a single regioisomer [1262]. Finally, condensation of **15b** with the diester of **10**, reduction of the Schiff base with sodium borohydride and hydrolysis leads to folic acid [1263].

The various schemes to synthesize folic acid are extensively discussed in [1225].

13.7. Metabolism and Biochemical Functions

Prior to absorption by the jejunum, dietary folylpolyglutamates are hydrolyzed to monoglutamates by folylpolyglutamate hydrolases (conjugases). Deconjugation occurs at the surface of the absorptive cells and within lysosomes in enterocytes [1264–1267]. Intestinal absorption and transport are optimal in a slightly acidic environment at pH 6 [1268]. A single protein seems to be responsible for the transport of the monoglutamates, as shown by competitive inhibition [1269]. Some conversion of folates, mostly to 5-CH_3-H_4folate, can occur during the passage across the intestinal mucosa and before release into the portal circulation. At pharmacological doses ($\geq$1 mg), significant amounts of folate appear unchanged in portal blood. They are converted to methylated forms in the liver [1270, 1271]. Apart from H_4folate and 10-HCO-H_4folate, mainly 5-CH_3-H_4folate is observed in blood, bound to plasma proteins such as albumin, α-macroglobulin, and transferrin (low-affinity binders). High-affinity folate-binding proteins are also known, but their functions are not yet well understood [1272, 1273]. The enyzme folylpoly-γ-glutamate synthetase converts folic acid to folylpolyglutamates and is located in the cytosol as well as in mitochondria [1274, 1275]. The liver exhibits the highest activity of this enzyme; appreciable amounts are also observed in most other mammalian tissues [1276]. Folylpolyglutamates seem to be the storage forms, but they can also increase the specificity of some folate-dependent enzymes. The enzyme dihydrofolate reductase transforms the different forms of folate to the active coenzymes, the tetrahydrofolylglutamates, whereby NADPH functions as hydrogen donor. Tetrahydrofolates are involved in a variety of biochemical processes, such as methylation reactions, amino acid metabolism and biosynthesis of purines and pyrimidines [1239, 1277]. They

acquire C_1 units at N-5 and/or N-10 and function as coenzymes in the transfer and utilization of C_1 fragments of different oxidation states, such as methanol, formaldehyde, and formate.

In humans, plasma levels of 7 – 17 µg/L are found. The concentration of folate in erythrocytes is ca. 200 – 500 µg/L. The total folate pool in adult humans is estimated to be ca. 5 – 10 mg, half of which is stored in the liver. The daily excretion of folate in urine is ca. 40 µg and in feces 200 µg [1278, 1279].

13.8. Nutritional Requirements and Medical Use

Recommended Daily Intake (RDI). Approaches that have been used to estimate folate requirements in humans are the determination of folate amounts needed to normalize the folate status after depletion, the evaluation of the average daily folate intake, the measurements of urinary metabolites, and kinetic studies. Based on several studies, the official recommendation in the United States was lowered in 1989 and is set at 3 µg/kg body weight per day, resulting in ca. 200 µg folate for adult males and 180 µg for adult females [1280]. Since pregnancy and lactation are often associated with poor folate status, 400 µg/d and 260 – 280 µg/d, respectively, is recommended. The recommended intake for infants from birth until 1 year of age is set at 3.6 µg/kg body weight per day (25 – 35 µg). This amount is also recommended for children between 1 and 10 years of age (50 – 150 µg). As pointed out by Bailey [1240], the present U.S. value [1280] may not be sufficient to maintain normal folate levels and will most likely have to be reevaluated.

Medical Use. Folate deficiency leads to impaired amino acid metabolism, protein synthesis, and cell division. The effects are most noticeable in growing tissue. A major clinical problem associated with folate deficiency is macrocytic anemia in which the bone marrow produces giant, immature red blood cells. An increased incidence of megaloblastic anemia has been reported during pregnancy and following child birth. Folate antagonists (e.g., methotrexate and certain antiepileptics) are used in therapy for various diseases, but their administration can lead to a functional folate deficiency. In cases of infections (e.g., protozoal infections in AIDS patients) or certain types of cancer (e.g., choriocarcinoma, cancer of the head and neck, childhood acute lymphocytic leukemia) high doses of 5-HCO-H_4folate (5 – 30 mg) may be given as "rescue dose" [1281–1283]. Precancerous conditions such as bronchial squamous metaplasia improved in some smokers after taking 10 mg/d [1284].

Homocystinemia is a heterogeneous group of inherited diseases of folate, vitamin B_{12}, and homocysteine metabolism and is associated with severe arteriosclerosis and thromboembolism as well as mental retardation. Of the inherited folate disorders, deficiency of methylenetetrahydrofolate reductase [1285] reduces or eliminates the generation of 5-CH_3-H_4folate, which is needed as cosubstrate to convert homocysteine to methionine by methionine synthase. In men with homocysteinemia, daily administration for 6 weeks of 1 mg folic acid, 10 mg vitamin B_6, and 0.4 mg vitamin B_{12} normalized serum homocysteine levels [1286]. In psoriasis patients receiving methotrexate, increased plasma homocysteine levels could be lowered with folic acid [1287, 1288]. In healthy men and women, a significant inverse correlation between plasma levels of folate and vitamin B_{12} and total plasma homocysteine was observed [1289, 1290].

Neural tube defects (NTDs), including spina bifida and anencephaly, are polygenic conditions. However, epidemiological studies have shown an increased incidence of NTDs associated with environmental factors. Several studies have provided evidence that multivitamin or folic acid (0.8 – 4 mg/day) supplementation prevents the majority of these NTDs [1291–1294]. Health authorities in the United States and United Kingdom advise women of childbearing age to take daily folate supplements of 0.4 mg [1295, 1296].

Toxicity. Daily oral supplementation with 5 – 10 mg of folic acid is not toxic for normal non-pregnant humans [1297]. Problems that might occur are the masking of vitamin B_{12} deficiency resulting in irreversible damage to spinal cord (subacute combined degeneration of the cord), and recurrence of epilepsy in epileptics treated with drugs with antifolate activity. A hypervitaminosis has not yet been reported. The

acute toxicity (LD_{50}) is 500 and 600 mg/kg body weight for rats and mice, respectively [1298].

Animal Nutrition. In animal nutrition, folic acid supplementation is required to obtain optimal performances of farm animals [1299]. Accordingly, doses of 0.2 – 0.5 mg/kg feed (dry matter) and 0.3 mg/kg for chickens and pigs are required, respectively. Under commercial production conditions, however, increased folic acid supplementation is recommended [1300]. Thus, the recommended amounts are 0.5 – 1.0 mg/kg feed for chickens and 0.5 – 2.0 mg/kg for swine.

13.9. Analysis

Analytical procedures, such as physicochemical, chromatographic, radioisotopic, and microbiological methods, are available to determine folate concentrations. However, analysis is still very difficult, because of the many naturally occurring derivatives and their rapid conversion by numerous enzymes, their lability, and the low amounts in biological samples. Methods for determining the C_1 unit, the reductive state of the cofactor, or the chain length of folylpolyglutamates are also important. For general discussions and detailed procedures see [1301–1303]. Pure folic acid, folate in enriched preparations or various monoglutamates can be measured by spectrophotometry, polarography, or HPLC [1304–1307]. Several microorganisms such as *Lactobacillus casei*, *Streptococcus faecalis*, or *Pediococcus cerevisiae* do not synthesize folate and can, therefore, be used to measure folate from natural sources [1308]. Since folylpolyglutamates with more than 3 glutamate residues are less active or inactive, hydrolysis of polyglutamate chains by γ-glutamyl hydrolase is required to obtain maximal growth of the microorganisms. Differential analysis of folates can be obtained by using *P. cerevisiae*, as this microorganism does not respond to nonreduced folate or 5-CH_3-H_4folate. To determine folateactive substances in erythrocytes and plasma, a number of radioisotope kits based on competitive protein binding are commercially available. Various folates, however, bind with different affinities to the corresponding folate binding proteins, resulting in determination of preferential folates. In addition, the results obtained with different test kits fluctuate considerably. Interpretation of the results with regard to the folate status may, therefore, pose problems.

13.10. Economic Aspects

The present world market for folic acid is ca. 400 t/a, commercially available as pure crystalline material (water content 8 %) or as premix. The major part (ca. 80 %) is used for feed enrichment in animal nutrition. The pharmaceutical industry offers folic acid for therapeutic and prophylactic use, either as a monopreparation or in combination with iron and/or other vitamins. Folic acid is also increasingly used for food enrichment (flour, cornflakes). The major producers of folic acid are Hoffmann-La Roche; the Japanese companies Takeda, Sumica Fine Chemicals (previously Yodogawa Pharmaceuticals), and Kongo; the Chinese companies Changzhou Pharma and Changshu Huagang Pharma; as well as some smaller companies in China, India, and Russia. The sales price in 1995 varied between € 36 and € 77/kg.

14. Niacin (Nicotinic Acid, Nicotinamide)

14.1. Introduction

Niacin is one of the vitamins of the B complex. In accordance with the rules on nomenclature the Institute of Nutrition [1309] suggested that niacin be used as the generic name for both nicotinic acid and nicotinamide.

Other commonly used names include pyridine 3-carboxylic acid and vitamin PP for nicotinic acid, and pyridine 3-carboxylic acid amide, pyridine 3-carboxamide, vitamin PP, and niacinamide for nicotinamide.

Nicotinic acid was first synthesized in 1867 by oxidative degradation of nicotine. It had been chemically identified long before its importance

as an essential nutrient (pellagra-preventing vitamin) was recognized [1310].

In the early 1900s it was discovered that pellagra, a disease with symptoms affecting the skin, gastrointestinal tract, and central nervous system, was caused by nicotinic acid deficiency. Experiments in 1917 with yeast, known for its high natural nicotinic acid content of up to 500 mg/kg, showed a curative effect on pellagra [1310, 1311].

In 1935 nicotinamide was shown to be a moiety of the coenzymes NAD (nicotinamide adenine dinucleotide) and NADP (nicotinamide adenine dinucleotide phosphate). These coenzymes are indispensable for many biochemical reactions in all living cells [1310].

Niacin is a naturally occurring substance. Nicotinic acid is the form present in food of plant origin, whereas nicotinamide occurs in animal products. Not all of the natural niacin is fully bioavailable for humans and animals. Nicotinic acid in cereals and in oil seeds is present in a bound complex. Average contents of niacin are in the range of 10 – 200 mg/kg of product.

The symptoms of niacin deficiency are usually described as a disease of the "three Ds": dermatitis, diarrhea, and dementia. However, the three Ds represent the last stage of the disease. The early stages include lassitude, impaired digestion, and inflammation of the mucous membranes of the mouth, stomach, or intestine.

In developed countries, pellagra symptoms are found in connection with chronic alcoholism and one-sided nutrition. Animals exhibit skin problems, diarrhea, weight loss and decreased feed intake.

Niacin is a component of multivitamin preparations, breakfast cereals, and soft drinks. Flour is enriched with niacin. For domestic animals niacin is an important part of compound feed. More than 60 % of the niacin produced is required by poultry, swine, ruminants, fish, and pets.

14.2. Physical and Chemical Properties

Physical properties of nicotinic acid and nicotinamide are summarized in Table 38. The acid and the amide differ substantially in melting point and solubility. Most producers guarantee stability of 2 – 3 years. However, nicotinamide is a hygroscopic substance and tends to form lumps. It is therefore recommended that storage, in a closed package and under cool, dry conditions, should not exceed six months. Aqueous solutions are stable, and sterilization is possible without special precautions.

Table 38. Physical properties of niacin

	Nicotinic acid	Nicotinamide
IUPAC name	pyridine 3-carboxylic acid	pyridine 3-carboxamide
CAS no.	[*59-67-6*]	[*98-92-0*]
Formula	$C_6H_5NO_2$	$C_6H_6N_2O$
Molecular mass	123.11	122.13
Appearance	white crystals	white crystals
Melting point	234 – 237 °C (>238 °C decomp.)	128 – 131 °C
Solubility in water	1.3 g/100 mL (15 °C)	38.3 g/100 mL (20 °C)
	9.8 g/100 mL (100 °C)	

14.3. Biochemical Functions

Niacin is absorbed almost completely by simple diffusion across the intestinal mucosa. The absorbed niacin is taken up by the tissues, and is thought to be incorporated directly into coenzyme forms.

Niacin serves as the precursor of two essential coenzymes: nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) [1310, 1312, 1313]. Both coenzymes catalyze the metabolic transfer of hydrogen – one of the basic functions in the metabolism of proteins, fats, and carbohydrates. This function is required for both the synthesis and degradation of amino acids, fatty acids, and carbohydrates.

Another important task of the niacin coenzymes is their repeated intervention in the citric acid cycle. The citric acid or Krebs cycle comprises many steps in which activated acetate is repeatedly oxidized.

Compounds originating from the degradation of fatty acids, carbohydrates and amino acids are first broken down to pyruvate oxalacetate and then enter the cycle with the active acetate. The various oxidative steps of the cycle yield a considerable amount of energy, which is stored in adenosine triphosphate (ATP). This energy can be released by conversion of ATP to adenosine

diphosphate (ADP), which is then ready to pick up more energy. Niacin thus plays an essential part in the metabolic production and utilization of energy.

14.4. Production

Industrial production of nicotinic acid and nicotinamide are based on the raw materials 5-ethyl-2-methylpyridine and 3-methylpyridine (3-picoline).

3-Methylpyridine is obtained by catalytic gas-phase reaction of acetaldehyde, formaldehyde, and ammonia (Figure 23). However, the principal product is pyridine, while 3-methylpyridine is obtained as a byproduct in 30 – 50 % yield. 5-Ethyl-2-methylpyridine is produced by reaction of paraldehyde with ammonia (→ Pyridine and Pyridine Derivatives, Chap. 2.2.6.).

Nicotinic acid is obtained directly by nitric acid oxidation of 5-ethyl-2-methylpyridine (Fig. 23) or by total hydrolysis of 3-cyanopyridine. Nicotinamide is available either from the amidation of nicotinic acid or from partial hydrolysis of 3-cyanopyridine. The latter is obtained by ammoxidation of 3-methylpyridine.

Oxidation of 5-Ethyl-2-methylpyridine. The world's largest plant for the production of niacin is located in Visp, Switzerland, and is operated by Lonza.

The principles of the Lonza process are summarized in the following and in the flow diagram of Figure 24 [1314]:

In an aqueous solution 5-ethyl-2-methylpyridine is oxidized to nicotinic acid in a single-tube reactor by using an excess of nitric acid. The continuous process takes place at 230 – 270 °C and 6 – 8 MPa. Pyridine-2,5-dicarboxylic acid is formed as an intermediate, but is not stable under the reaction conditions, undergoing decarboxylation to nicotinic acid nitrate. Neutralization of the nitrate with 5-ethyl-2-methylpyridine yields nicotinic acid. Water and carbon dioxide formed in the reaction are separated from the product. The nitrogen oxide formed is oxidized with air to nitrogen dioxide and then absorbed in water to yield nitric acid, which is recycled into the process.

Ammoxidation of 3-Methylpyridine and Hydrolysis of 3-Cyanopyridine (→ Pyridine and Pyridine Derivatives, Chap. 3.7.).

In a multitubular reactor 3-methylpyridine, air, ammonia, and hydrogen react at ca. 350 °C and moderate pressure to give 3-cyanopyridine [1315]. Heterogenous catalysts containing oxides of antimony, vanadium and titanium [1316] or antimony, vanadium and uranium [1317] are highly effective and commonly used. For instance, with an antimony – vanadium – titanium catalyst, a reactor temperature of 360 °C, and a molar feed ratio of 3-methylpyridine : ammonia: air : water of 1 : 6 : 30 : 6 yields 96 % of 3-cyanopyridine [1318]. 3-Cyanopyridine is converted to nicotinamide by alkaline hydrolysis. This reaction has the advantage that saponification to the amide is fast compared to total hydrolysis to nicotinic acid. The hydrolysis to the amide is normally carried out with catalytic amounts of bases, mainly sodium hydroxide, at 130 – 150 °C [1319]. Other catalysts are also mentioned. A copper – chromium oxide catalyst gives good yields of nicotinamide [1320].

Conversion of 2-Methylglutaronitrile. 2-Methylglutaronitrile, a byproduct of adiponitrile production, is converted to 2-methyl-1,5-diaminopentane. Cyclic hydrogenation gives 3-methylpiperidine. Dehydrogenation yields 3-methylpyridine [1321], which is then ammoxidated and partly hydrolyzed to nicotinamide.

14.5. Quality Specifications

Nicotinic acid and nicotinamide are available in various forms. Pharmaceutical grade meets the requirements of current pharmacopoeias, and food grade, which is usually equal to pharmaceutical grade in quality, meets the standards of USP and FCC (Food Chemical Codex). These products have an assay of >99.8 % of the active substance. The technical and feed grades of the leading producers have a purity of min. 99.5 % (nicotinic acid) and min. 99 % (nicotinamide). Lonza offers a DC quality (DC = direct compression), which is preferably used in the tabletting of vitamin or multivitamin tablets without auxiliary substances, thus improving the process in terms of energy consumption and production time.

There are only minor differences in product quality caused by variations in production processes or in the raw material used.

14.6. Analysis

Assays of the pure substances are most readily determined by titration. Nicotinic acid is determined by titration with sodium hydroxide [1322] or UV spectroscopy [1323]. Nicotinamide is determined by titration with perchloric acid in acetic acid [1324] or UV spectroscopy [1325]. For the pharmaceutical grade, the official standards of purity of the pharmacopoeias, such as USP [1323, 1325] or European Pharmacopoeia [1324, 1326] apply.

To ensure a vitamin supply oriented to meeting requirements in human and animal nutrition, foods and feeds are enriched with niacin or mixtures of vitamins. Microbiological [1327], spectrophotometric [1328], and chromatographic [1329] procedures are described for the quantitative determination of nicotinic acid or nicotinamide in foods and feeds. A most suitable method is the AOAC spectrophotometric method [1328]. Microbiological methods and the above-mentioned photometric method have the disadvantage that only the total amount of nicotinic acid and nicotinamide can be detected. With HPLC it is possible to determine the single compounds [1330, 1331].

14.7. Uses

Pellagra in humans was formerly widespread in many parts of the world where corn was the main source of nutrition. Subclinical symptoms of deficiencies still appear under conditions of malnutrition or one-sided nutrition. Recommended dietary allowances for humans are listed in Table 39 [1332].

Table 39. Recommended dietary allowances for niacin

	Age, a	Weight, kg	Niacin, mg/d
Infants	0 – 0.5	6	5
	0.5 – 1	9	6
Children	1 – 3	13	9
	4 – 6	20	12
	7 – 10	28	13
Men	11 – 14	45	17
	15 – 18	66	20
	19 – 24	72	19
	25 – 50	79	19
	>51	77	15
Women	11 – 14	46	15
	15 – 18	55	15
	19 – 24	58	15
	25 – 50	63	15
	>51	65	13
Pregnant women			17
Nursing mothers			20

Enrichment of cereal products with B vitamins, especially with nicotinic acid or nicotinamide, became feasible in the early 1940s when the vitamin became commercially available, and is now standard practice [1333]. Niacin is present in breakfast cereals, multivitamin drinks, and multivitamin tablets [1334].

Niacin is also essential to most animals [1335]. The requirements can be covered by various sources. Biosynthesis from tryptophan is not of importance since the conversion rate is very low and most natural feedstuffs are relatively poor in this amino acid. Nicotinic acid

Figure 23. Industrial production of nicotinic acid and nicotinamide

Figure 24. Flow diagram of the oxidation of 5-ethyl-2-methylpyridine to nicotinic acid (Lonza process)
a) Reactor feed preparation; b) Piston pump; c) Steam-heated reactor; d) Separator; e) Air compressors; f) Absorption columns for nitrogen oxides; g) Concentration column; h) Condensor; i) Crystallization; j) Centrifugation; k) Dissolver; l) Neutralization; m) Crystallization; n) Tray dryer

is synthesized by the microflora in the large intestineof monogastrics and in the rumen of ruminants. In monogastrics, biosynthesis is insignificant because it occurs in the large intestine, located after the main niacin-absorption sites of the duodenum and small intestines. Most of the nicotinic acid synthesized by the microflora is therefore excreted in the feces. Synthesis of nicotinic acid in the rumen is suboptimal when the animals are under stress for high production or when the rumen microflora has been disturbed. The nicotinic acid production by the ru-

men microflora may be affected by antiobiotics and other feed additives.

Niacin deficiency reduces the activity of the coenzymes NAD and NADP, resulting in metabolic disorders and hence in reduced weight gain, decreased feed intake, reduced feed efficiency, health problems (e.g., ketosis), and impaired reproduction.

To achieve peak performance and to maintain good health all domestic animals and pets need a dietary source of niacin to meet their requirements. Niacin levels should therefore be higher than the NRC (National Research Council) recommendations [1336], because it is generally accepted that the NRC recommendations are based on ideal dietary and management conditions, since no safety margin is included or limited bioavailability considered. Recommendations for niacin addition to animal feed (in mg/kg feed) are summarized in the following [1335]:

Poultry	
Chicks	50
Broilers	60
Hens (laying)	40
Hens (breeding)	50
Turkeys (starting)	90
Turkeys (growing and fattening)	80
Turkeys (breeding)	80
Ducks and geese (starting)	50
Pigs	
Piglets (early-weaned)	40
Piglets (starting)	35
Pigs (growing)	35
Pigs (fattening)	30
Sows (breeding)	35
Ruminants	
Calves (0 – 3 months)	60
Cattle (fattening)	1000 mg per animal per day
Dairy cows	3000 – 6000 mg per animal per day
Sheep and goats	1000 mg per animal per day
Horses	
Foals and yearlings	40
Working horses	90
Race horses	90
Pets	
Dogs	25
Cats	70
Fish	
Cyprinids	100
Salmonids	200
Shrimps	200
Others	
Rabbits	50
Mink	50
Foxes	50

Nicotinic acid and nicotinamide used in doses in excess of nutritional requirements generate a number of readily recognizable pharmacological responses, some of which are of therapeutic significance. In view of the relationship of nicotinic acid to nicotinamide it is remarkable that few if any of the considerable pharmacological activities of nicotinic acid are shared by nicotinamide.

Some of the observed effects of pharmacological doses of nicotinic acid are as follows:

1) Effects on lipid metabolism: Plasma cholesterol and triglycerides concentrations fell significantly with 1 – 3 g/d doses of nicotinic acid [1310, 1337, 1338]. Different products with nicotinic acid or esters of nicotinic acid are commercially available.
2) Vasodilation: The flush reaction caused by the increased blood flow rate appears very quickly [1310, 1313]. This effect is also used in medicine [1310, 1313] (e.g., in treatment of smokers' legs).
3) Activation of fibrinolysis [1310].

Pharmacological doses of nicotinamide have been shown to improve islet-cell regeneration and appear to have a protective effect on residual insulin secretion in Type 1 diabetic patients. Thus, it is conceivable that nicotinamide may have a place in preventing diabetes in predisposed subjects [1339].

Niacin is used in electroplating baths. Zinc electroplating baths contain niacin in a quaternized form obtained by the reaction of niacin with benzyl chloride, resulting in uniform and brilliant surfaces.

14.8. Economic Aspects

In 1995, ca. 22 000 t of nicotinic acid and nicotinamide were produced worldwide. 16 000 t or ca. 75 % of total niacin production was used in animal nutrition and 6000 t as food additive. The most important markets are the United States with a market share of 35 – 40 %, followed by Europe with 30 %, and Japan and South East Asia with 20 %.

Table 40 shows the development of the niacin market over the last 25 years. Producers of nicotinic acid and nicotinamide and their capacities are presented in Table 41.

Table 40. Niacin market 1970 – 1995 in t

	1970	1980	1995
Nicotinic acid	3000	9 000	14 000
Nicotinamide	1000	3 000	8 000
Total	4000	12 000	22 000

Table 41. Producers and their capacities of nicotinic acid and nicotinamide in 1995

Producer	Location	Nicotinic acid, t/a	Nicotinamide, t/a
Lonza	Visp, Switzerland	13 000	1500
	China ∗∗		3000
Vitachem ∗	Antwerpen, Belgium	1 000	3500
	Indianapolis, USA		3500
Nepera	Harriman, USA		3000
Yuki Gosei	Japan	200	1000
Others		1 000	500

∗ Joint Venture of Degussa and Reilly Tar.
∗∗ Joint Venture of Lonza/GPF Guangzhou, start-up planned for 1998.

Demand for niacin is rising by ca. 2 – 3 %/a in the industrialized countries, while it is soaring by as much as 10 %/a in the developing and newly industrialized countries.

14.9. Toxicology

Nicotinic acid and nicotinamide are essential for human and animal health. The daily requirement to avoid deficiencies in humans is in the range of 15 – 30 mg. For the treatment of hyperlipoproteinemia and hypercholesterinemia daily doses up to 6000 mg of nicotinic acid are used [1337].

Nicotinic acid and nicotinamide are acutely nontoxic (oral LD_{50} greater than 5000 and 3000 mg/kg in rats, respectively), not irritant to the skin but moderately irritant to the eye of rabbits [1340].

Nicotinic acid, up to 1000 mg kg^{-1} d^{-1}, did not show either cumulative toxicity in a 28 d oral study or teratogenicity in rats [1340]. No mutagenicity was found in a battery of mutagenicity tests [1340], and no carcinogenicity was observed in mice treated for a lifetime with nicotinic acid in drinking water [1341].

Rare cases of skin flushing may occur in humans, but this effect is reversible after termination of exposure to nicotinic acid.

Nicotinic acid is practically nontoxic to fishes, daphnia, algae, and bacteria and is readily biodegradable [1340].

Based on the available information nicotinic acid and nicotinamide do not represent a hazard to humans or the environment.

1. Introduction

For the examination and control of a process, the process parameters must be measured without interfering with the process. Nevertheless, it is necessary to obtain as much information on the physical properties of the process as possible. Often the spatial distribution of a fluid, a temperature, or a concentration has an important impact on product quality and process efficiency. Local measurement techniques, can only measure the physical properties at certain locations, and often interference of the process by the measurement sensor can not be avoided. To obtain information on a complete cross section of an apparatus, numerous measurements must be taken by placing the measurement probe at different locations. Therefore, only time-averaged information is available, and this can lead to misinterpretations, especially for nonstationary flows. To overcome these intrinsic measurement problems, in process engineering there is a need for measurement techniques which provide high time and spatial resolution over a complete cross section of an apparatus without interfering with the process.

2. Optical Visualization Techniques

Numerous optical techniques have been used to obtain two-dimensional images of different kinds of flow. Their major advantages are nonintrusive measurement and high spatial and time resolution. However, their application is limited because the optical accessibility of the measurement object has to be guaranteed. Besides visible light, as in video or high-speed camera observations, nonvisible light is used for various optical measurement techniques. Details on optical measurement techniques for process engineering applications are described in [111].

In Raman spectroscopy the measurement plane is illuminated by monochromatic light. If a molecule is hit by a light photon it is lifted into a higher energy state. After a very short time, the molecule emits the photon and returns to its original state. If the emitted photon has a different energy to the absorbed photon, its wavelength shifts. Depending on the shift, different types of scattering (e.g., Stokes and anti-Stokes Raman scattering, Rayleigh scattering) can be observed. The analysis of the different types of scattering leads to the measurement of temperature or concentration fields.

The effect of thermal radiation is used in measurement techniques like thermography and pyrometry. Depending on its temperature, a body has a certain radiant emittance. This is measured by radiation detectors, which are suited to different radiation wavelengths. For calculating the temperature of a body, various influences on the measurement result have to be taken into account. These are the material and surface properties of the examined material, the Kirchhoff radiation laws, and the dependence of the radiation on the emission angle. Such measurement

systems are used for the two-dimensional imaging of temperature fields.

Three-dimensional information can be collected by using holographic measurement techniques (see also → Holography). The object to be measured is illuminated by monochromatic light, which is scattered and reflected by the measurement object onto a photographic plate. At the same time, part of the monochromatic light is led directly from the light source to the photographic plate, so that it does not interact with the measurement object. On the photographic plate the two light beams, called the object and reference beams, form a stable interference pattern, which is stored on the plate. When the plate is illuminated by the reconstruction beam, which has the same physical properties as the reference beam, the measured object is reconstructed three dimensionally and can be viewed from different angles.

For the measurement of temperature or concentration profiles, the reference and the measurement beam are collected at different times. First the reference beam is led through the measurement plane and stored for the initial state of flow. After a change in temperature or concentration, and therefore a change in the refractive index of the flow, has occurred, the measurement beam is recorded. This causes an interference pattern on the photographic plate. Analysis of the patterns leads to the temperature or concentration field in the flow.

By taking holograms of an object from two directions, its position can be assessed by cutting the two holograms into slices and comparing them to each other. This kind of technique provides high spatial and temporal information on the process and has been successfully employed for measuring particle sizes and velocities in sprays and bubbly flows [123]. To measure the particle speed, two holograms are taken at short intervals. By comparing the two holograms, the paths of the particles and their velocity vectors can be measured.

For measuring two-dimensional velocity fields in flows of different types, particle image velocimetry (PIV) has become a valuable tool. From the velocity field, further information such as vorticity, pathlines, and Reynolds stresses can be derived. For imaging, the measurement volume is illuminated with a laser sheet for a short time. The illuminated sheet is photographed by a CCD camera and stored on a PC. This procedure is repeated after a certain time to obtain information on the change of flow. By processing the stored images (in the simplest way, by cross-correlation of two images) the velocity field in the illuminated part of the flow can be calculated. For the application of PIV in two-phase flow, special algorithms for the detection of gaseous or liquid particles have been developed. In addition, various algorithms for the calculation of the flow field are available. For an overview of PIV techniques, see [124, 125].

3. Tomographic Visualization Techniques

Tomographic measurement techniques have become increasingly popular in chemical and process engineering. With such techniques, fields of density, concentration, temperature, velocity, or local void fraction can be measured without interfering with the flow in the measurement plane. The measured fields are often nonstationary and may even have a transient character. Therefore, the tomographic measurement techniques must have high spatial and temporal resolution.

The term tomography originates from the Greek *tomos* (slice) and *graph* (image). Thus, goal of tomographic measurement is to generate a two-dimensional image of a cross section of the measurement object. The two-dimensional image contains information on the distribution of a physical property. For medical applications this is the texture of tissue or the water fraction therein. Tomographic measurements have two major advantages over other techniques. First, the measurements are conducted without interfering with the measurement object, and second, that the target quantity is measured simultaneously at many places in the measurement plane.

The application of tomographic measurement techniques in process and chemical engineering is, in comparison to the medical sector, relatively new. Developments in the design of sensors and in reconstruction techniques have been the subject of international conferences [2–10]. These symposia dealt with the measurement of density fields and the measurement of the void fraction field in single- and multiphase flows. Currently these techniques are mainly used for scientific and research applications, but there are

already potential applications in industry. For example, they are used for the measurement of the phase distribution in the exploitation of natural oil and gas.

In Figure 1 the tomographic measurement is depicted schematically. On the left, a chemical reactor filled with a solid catalyst is depicted. At the top of the reactor, gas and liquid are introduced and flow cocurrently through the catalyst, on which a chemical reaction takes place. The homogeneous distribution of the liquid phase is an important factor affecting the quality and the efficiency of the chemical reaction. The tomographic measurement allows a slice to be taken out of the reactor, as is depicted on the right of Figure 1. The solid catalyst is depicted in gray, the liquid phase in blue, and the gas phase in white. The location of the three different phases can be readily detected. Therefore, a detailed analysis of the phase distribution is possible, which helps to improve such chemical reactors with regard to the quality of the product and the consumption of the starting materials.

Figure 1. Schematic of tomographic measurements in a trickle-bed reactor

The choice of the tomographic techniques for a given measurement task depends on the physical properties of the fluids to be measured and the required time and spatial resolution. Medical tomography systems often cannot be used, in spite of their high spatial resolution, because their measurement time is too long for nonstationary multiphase flows. Therefore, new measurement techniques with high temporal and sufficient spatial resolution must be developed. Goals of current research and development programs are improving the spatial resolution of the electrical tomographic techniques and the temporal resolution of the X-ray techniques.

3.1. Tomographic Measurement Systems

The tomographic measurement is performed in two consecutive steps, depicted schematically in Figure 2. Figure 2a shows the steps which have to be performed for the tomographic imaging, and Figure 2b shows the tool used. In the first step integral measurements of the property field in the measurement plane are performed by the tomographic sensor and the data-acquisition system. The measured values contain information on the property field inside the sensor. After the measurements have been made, the local measurement property is calculated from the measurement values (reconstruction). The obtained measurement result represents the property field in the measurement plane.

Integral Measurement. Figure 3 shows the integral measurement of the property field for a linear tomographic system. The goal of the integral measurement is to obtain the measurement values $\boldsymbol{\Phi}_{\mathrm{M}}$ which are dependent on the property field $g(x,y)$ in the measurement plane. The measurement plane is illuminated by a beam, which is attenuated by the material inside. The beam can be a X-ray or a γ-ray beam as well as a beam of light, depending on the material in the measurement plane. If many measurements are taken in one direction, a projection is obtained. By rotating the measurement device or by mounting many beam sources and detectors, linearly independent projections in different directions are obtained. This yields the measurement vector $\boldsymbol{\Phi}$, which contains the information on the distribution of the physical property inside the measurement plane.

To generate the measurement vector, different techniques can be used. In Tables 1, 2, 3 an overview of the tomographic techniques is given. The techniques are classified according to the physical interaction between the sensor and the material inside. In principle, different physical interactions can be used for the measurement as depicted in Figure 4. In the case of transmission (Figure 4a) the physical property

Figure 2. Schematic description of the tomographic measurement

Figure 3. Integral measurement for a linear tomography system

of the electromagnetic wave or particle radiation emitted by the source is influenced by the material in the measurement plane. The change in the physical property is measured by the receiver mounted on the opposite side of the sensor. The physical property that changes can be the intensity, the polarization, or the run time of the beam. In emission techniques (Figure 4b) the intensity and the spatial orientation of the radiation emitted from the measurement plane is measured. The material in the measurement plane is itself the source of the radiation. The radiation can be natural or the result of external excitation. In reflection techniques the position and the change in the physical property of a wave or a particle that has been reflected from an interface are measured. Similar to the reflection techniques, for the refraction and diffraction techniques, the change of the direction or the physical property of a wave or particle radiation at a discrete or continuous interface in the measurement plane is measured. Particle radiation or high-energy electromagnetic waves cause scattering effects when they strike molecules or atoms. These scattering effects can also be used for tomographic measurements. In this case the statistical distribution of the property vector as well as its orientation are measured.

Table 1. Electrical tomographic techniques in process engineering [11]

	Electrical capacitance tomography (ECT)	Electrical resistance tomography (ERT)	Electromagnetic inductive tomography (EMT)	Microwave tomography
Parameters measured	capacitance and loss angle at high frequencies (1 MHz)	resistance and phase angle at low frequency (1 – 500 kHz)	independent measurements of magnetic permeability and eddy current loss (50 Hz – 5 MHz)	real and imaginary components of complex permittivity (2 – 3 GHz)
Parameters derived	solids: volumetric concentration, moisture profiles gases: concentration profiles	solids and gas volumetric concentration profiles	separate volumetric concentration profiles of ferrous and nonferrous materials	structural integrity, physical parameters, e.g., water content, temperature
Applications	pneumatic conveyors, fluidized beds, combustion imaging, foams, oil/gas flows	hydraulic conveyors, solid/liquid mixers and separators, liquid/gas flows, liquid/liquid flows	metallurgical processes, location of ferrous and nonferrous contaminants in products, particle population tomography (ferrous labels)	conveyed products, wood, paper, pipes, buried objects
Speed	100 frames/second	200 frames/second	100 frames/second	100 frames/second
Resolution	5 – 10 % of vessel diameter	3 – 6 % of vessel diameter	5 – 10 % of vessel diameter	10 – 20 % of vessel diameter
Slice thickness	> 25 cm or diameter/ 10	diameter/ 10	diameter/ 5	diameter/ 10
Vessel diameter	with present electronics max. 1 m, no theoretical limit	no theoretical limit, typically 1 mm to 3 m	200 mm	no theoretical limit
Cost	low	low	low (expensive if magnetic screen is used, without screening similar to ECT)	medium
Notes	electrodes are not in contact with the fluid, no electrically conducting material is allowed in the measurement plane, reconstruction of the images is complicated due to the nonlinearity of the electrical field	electrodes are in contact with the fluid, special: wiremesh sensor	at research stage, no electrodes	most suitable for thin slabs of material

Figure 4. Physical interactions used for tomographic measurement

Reconstruction. The measurement vector $\boldsymbol{\Phi}$ implicitly contains the information of the measured property field $g(x, y)$. The information is extracted in the second step of the tomographic measurement process, known as reconstruction. During reconstruction, the property field $g(x, y)$ is calculated by a mathematical inversion of the measurement process. If the measurement vector is as large as the number of unknown elements of the property field, a complete direct calculation of the property field is possible. In process engineering applications, the number of measurements is very low, to achieve a short measurement time. Therefore, the reconstruction of the property field has to be conducted with mathematical approximations.

In Figure 5a the measurement process is depicted schematically. The goal of reconstruction is the mathematical inversion of the measurement process, which is depicted in Figure 5b. Usually there are more unknown properties in the property field, than measurement values. Therefore, to improve the quality of the reconstruction, iterative techniques have to be used.

Table 2. Radiation tomography in process engineering [11]

	γ-ray	X-ray	Optical attenuation/emission	Optical diffraction	Positron emission	Positron emission/particle tracking
Parameters measured	photon attenuation	photon attenuation, Compton scattering	received light intensity	refractive indices of fluides	distribution of pairs of back-to-back γ-rays	pairs of back-to-back γ-rays from single tracer particle
Parameters derived	mass concentration profiles	mass concentration profiles	profile of absorbent concentration or temperature	density, temperature, concentration profiles	concentration field or radioactive tracer	trajectory of tracer particle
Applications	gas – solid – liquid processes	gas – solid – liquid processes	discontinuous phase in liquid or flames, mixing	mixing, heating of viscous fluids, flames, density fields near impeller flames	steady state segregation	solids mixing
Speed	depending on the spatial resolution needed: 90 to 30 frames/second	depending on the resolution needed: few seconds to 2000 frames/second	high	ca. 15 s	1 h for 3D volume image	100 locations/s
Resolution	1 mm for rotating scanner	$<$ 1 mm	1 – 2 mm	2 mm	8 mm in 3D	depends on trace speed: 5 mm at 1 m/s
Slice thickness	$<$ 5 mm	$<$ 5 mm	1 – 2 mm	2 mm	8 mm in 3D	depends on trace speed: 5 mm at 1 m/s
Vessel diameter	200 mm	$<$ 1 m	no theoretical limit	$<$ 100 mm	$<$ 600 mm	$<$ 600 mm
Cost	high	high	low	high	high	high

These require a mathematical description of the measurement process, which is depicted in Figure 5c. With this mathematical description, the theoretical measurement vector is calculated and compared to the actual measurement vector. The difference between the two leads to a change in the property field from which a new theoretical measurement value can be calculated. This iterative process of calculating and comparing the measurement vectors and correcting the property field is continued until the difference between the two measurement vectors is below a certain error margin.

Figure 5. Schematic of the reconstruction process

In Table 4 the known reconstruction techniques are listed. In principle, they can be divided into series expansion, inversion, and adaptive techniques. In series expansion techniques, the field function $g(x, y)$ is discretized. By using a mathematical description of the measurement process, a set of linear equations with the known measurement values and the unknown property field is then developed. In inversion techniques, the measurement process is mathematically inverted by using simplifications and preprocessing the measurement values. The discretization of the property field $g(x, y)$ is often not necessary. For the adaptive techniques, a detailed mathematical description of the measurement process is often not necessary. The algorithm is trained by a priori knowledge to reconstruct the property field.

Spatial and Temporal Resolution. The choice of the tomographic measurement system which is most suitable for a given measurement task is not only dependent on the technical limitations arising from the surroundings of the measurement (pressure, temperature, and material properties of the fluids and the apparatus), but also on the desired spatial and temporal resolution. The latter two parameters are coupled to each other. High temporal resolution results in a low spatial resolution, and vice versa. The spatial and temporal resolutions of the tomographic techniques are qualitatively compared to each other in Figure 6.

The classical tomography systems, such as X-ray tomography, positron emission tomography, and nuclear magnetic resonance tomography, have high spatial resolution. In contrast, their time resolution of 1 s to 30 min is rather low. For material science applications, particle-radiation techniques are quite commonly used because of their high energies, but their time resolution is even worse than those of the medical techniques. Current high-speed X-ray tomography systems are very expensive and have a relatively low spatial resolution.

For the application of tomographic measurement techniques in multiphase flows, especially those with rapidly changing flow patterns, high time resolution is essential. This can be realized by using optical techniques, which are limited to transparent measurement locations and to fluids that have the same refractive index. This can only be achieved for a few applications. In comparison to the above-mentioned techniques, the electrical tomographic techniques have a high temporal resolution and can be applied in most technical surroundings. The high temporal resolution can be achieved because the sensors have no moving parts and electrical components have short switching times. The relatively low spatial resolution of these techniques is generally sufficient for the applications.

3.2. Capacitance Tomography

The measurement principle of capacitance tomography is schematically depicted in Figure 7. Electrodes are mounted peripherally along the circumference of the measurement plane. The integral measurement values are taken by measuring the capacitance between two or more electrodes. The measured capacitance is dependent on the permittivity field inside the sensor. If the permittivities of the fluids inside the sensor are different, they can be distinguished from

Table 4. Reconstruction techniques

Reconstruction techniques [66–68]

Figure 6. Qualitative comparison of the spatial and temporal resolution of tomographic measurement systems

each other by the tomographic measurement (e.g., water and air have a relative permittivity ratio of 1 : 80). Capacitance can be measured by various electrical measurement circuits, e.g., the sender electrode is charged and the current at the receiver electrode is measured. Table 5 lists applications of capacitance tomography in process engineering.

The electrical field inside the measurement plane is described by the Poisson equation

$$\nabla^2 \varphi(x,y,z) + \frac{1}{\varepsilon(x,y,z)} \operatorname{grad} \varphi(x,y,z) \operatorname{grad} \varepsilon(x,y,z) = \frac{\varrho(x,y,z)}{\varepsilon(x,y,z)} \quad (1)$$

The right side of Equation 1 contains the source terms for a free charge carrier in the measurement plane. For most applications the fluids are without electrical charge and therefore the right side of the equation can be set to zero. The left side of the equation consists of the Laplace and Newton equations. The Laplace equation is valid for homogeneous permittivity fields and is extended to nonhomogeneous permittivity fields by the Newton equation. The capacitance is calculated by Equation 2

$$C = \frac{\int\int_A \varepsilon(x,y,z) \operatorname{grad} \varphi(x,y,z) \, \mathrm{d}\hat{A}}{\int_s \operatorname{grad} \varphi(x,y,z) \, \mathrm{d}\hat{s}} \quad (2)$$

which is the shift of the charge on the surface of an electrode divided by the potential difference along the line between a pair of electrodes. It is evident from Equation 1 that the relation between potential and permittivity is linear with

Table 5. Applications of capacitance tomography [15]

Phases	Application	Fluids	Dimensions	Refs.
Gas – liquid	horizontal plug – flow	kerosene – nitrogen	$d_i = 154$ mm	[91] [12,92]
		oil – air water – air	$d_i = 54$ mm	[93]
Gas – solid	pneumatic transport	air – sand	$d_i = 84$ mm	[94] [95]
	fluidized bed	air – sand air – PS	$d_i = 150$ mm	[96] [97]
			$d_i = 800$ mm	[98] [99]

Gas – liquid – solid	phase separator	air – foam oil – water – slurry		[101] [102]
Gas – liquid – liquid	three – phase – flow	oil – water – gas	$d_i = 82$ mm	[103]
Gas – liquid	trickle-bed reactor	water – air	$d_i = 120$ mm	[104]

respect to the potential, but nonlinear with respect to the permittivity. In addition the capacitance between a pair of electrodes depends on the permittivity field in the entire measurement plane. This makes the reconstruction of the permittivity field more complicated in comparison to other sonographic techniques, as depicted in Figure 8. In Figure 8a the relation between the property field and the measured physical value is depicted for a linear tomographic system, e.g., X-ray or optical tomography. The measured attenuation of the beam is only dependent on a small part of the measurement plane, because the radiation beam follows a straight path from the sender to the receiver. The relation between the attenuation of the beam and the density field inside the sensor is only dependent on the density field. Because of this, the reconstruction of such measurement data is comparatively easy.

In Figure 8b the measurement process for capacitance tomography is depicted. The measured capacitance is dependent on the permittivity field of the entire measurement plane. In addition, the electrical field is distorted by the permittivity field, which results in a change in the field lines or the potential lines. According to Equation 2, this results in a change in the capacitance. Therefore, the reconstruction of the capacitance tomography systems has to be performed with more sophisticated algorithms. The two algorithms most widely used for the reconstruction of capacitance measurement are linear backprojection [92, 105–107]and the ART algorithm. Other methods include model-based reconstruction [103, 108, 109], neural networks [110], and pattern association [14, 93].

Figure 7. Measurement principle of capacitance tomography

Before the reconstruction is performed, it has to be taken into account that the measurement values are taken segmentally and that the flow is therefore moving on while the measurements are taken. This is implemented, by a time and spatial correction [15]. The measurement values of each combination of electrodes is approximated by a fitting function. Then the measurement value of each combination is available at any desired time. If the velocity of the flow is known, the measurement values can be calculated at the time when the slice of the flow which is to be reconstructed was in front of the electrodes.

3.3. Conductive Tomography

In conductive tomography the electrodes are generally mounted peripherally around the measurement volume. They are mounted flush with

Figure 8. Comparison of linear and nonlinear tomographic measurement techniques

the wall and in direct electrical contact with the flowing fluid phases [16, 17]. Depending on the techniques, either a constant current is induced and the resulting potential at the other electrodes is measured, or a constant potential is applied to two electrodes and the resulting current measured. Therefore, the electrical properties measured have a nonlinear dependence on the phase distribution. In addition, this techniques requires full contact of the electrodes with the conducting phase.

A different conductive tomographic technique is depicted schematically in Figure 9 [18]. The sensor consists of three planes of parallel wires which are strung across the measurement plane. The three planes are shifted relative to each other such, that the measurement plane is segregated into small equilateral triangles. The conductance measured between two adjacent wires is dependent on the distribution of the fluids between the wires. By measuring the conductance between all wires, three projections of integral measurement values are obtained, which are used for the reconstruction of the conductivity distribution inside the measurement plane.

Figure 10 shows the measurement result for a single slug in horizontal gas – liquid slug flow. By stacking the measured and reconstructed images obtained by the tomographic measurement, an Eulerian representation of the phase distribution of the slug is obtained. This Eulerian representation can be used to compare the measured and reconstructed slugs to visually observed ones. In Figure 10a the side view of a slug is given. The direction of flow is from right to left. The mixing zone at the front of the slug is clearly visible. In order to compare this visual observation to the result of the tomographic measurement, two Eulerian plots are shown in Figure 10b and c. Two surfaces with different liquid contents are shown. The dark colored surface encloses regions with a liquid holdup over 0.5. The light colored surface represents a liquid holdup of 0.1. The slug is also represented in a side view, with the direction of flow from right to left. The surfaces are transparent, so that the mixing zone at the slug front and the gas bubbles entrained there can be seen. From visual comparison it is evident that the characteristic slug properties, in particular the shape of the mixing zone, are captured by the tomographic technique.

3.4. Optical Tomography

An overview of optical tomography is given in [111]. Jet mixing processes have been investigated by measuring the concentration of a dye by optical tomography [112, 113]. Temperature fields have been obtained from the phase shift of four laser beams passing through the flow field [114]. The phase shift depends on the refractive index, which in turn depends on the temperature of the fluid in the mixing tank.

Two lasers of different wavelength have been used to measure the micro- and macrotransport processes in the mixing of viscous liquids [115]. A mixture of an inert dye (Duasyn Acid Ponceau: red) and a dye that is decolorizes by a chemical reaction with the vessel contents (iodine: blue) are fed into the vessel. The rate of the

Figure 9. Measurement chain for conductive tomography with a wire-mesh sensor [18]

decolorization reaction is limited by micromixing. The local intensity of segregation is therefore obtained by comparing the local concentration of the reacting dye with that of the inert dye. Macromixing leads to equal dilution of both dyes, where as micromixing only reduces the concentration of the reacting dye. The three-dimensional transient concentration fields of both dyes are measured by tomographic absorption spectroscopy. The mixing vessel is illuminated from three directions with two superimposed laser beams of different wavelength. The absorption of the laser beams depends on the absorption coefficients of the dyes and on their concentrations along the beams. The light absorption is measured for all projections. From the measurement data the dye concentration is reconstructed in 1200 elements per plane of the vessel, and the vessel is divided into 30 planes. Thus, the local dye concentrations and the local intensity of segregation can be detected at 36 000 locations in the vessel.

In Figure 11 the initial measurement result is depicted in a quasi three-dimensional representation. The impeller was a Rushton turbine. The inert and reacting dyes can be clearly distinguished from each other. Five seconds after injection of the dye into the vessel, effective mixing has not taken place. The dyes stay in the main vortex caused by the impeller, so that the concentration of red dye in the middle plane is still high. In addition, due to the slow macrotransport, micromixing is also not effective. The blue iodine droplet is only stretched in the circumferential direction, resulting in a slow diffusive transport. With the tomographic measurement system, the mixing process can be observed fully three dimensionally, and insight into the efficiency of micro- and macromixing can be obtained at the same time.

Figure 10. Tomographic measurement result for horizontal gas – liquid slug flow

3.5. X-Ray Tomography

X-ray tomography is quite widely distributed for medical diagnosis and material science applications but is rarely used for the measurement

and control of processes. As the available equipment has rather long measurement times, it only can be used for the measurement of stationary or quasistationary processes. With new developments in positioning systems and computer technology, measurement times in the order of a few seconds are possible. With a high technical and financial effort measurement times of a few milliseconds can be attained [33]. With such systems, X-ray tomography becomes a valuable tool for the measurement of nonstationary multiphase flows.

X-ray tomography has already been successfully used for process engineering applications, for example, investigations of porosity and dispersion coefficients [116, 117] nonstationary multiphase flows [118], and gas – liquid flows in pipes [119, 120]. The temporal resolution of these measurements is about one minute with a spatial resolution of a few centimeters.

Figure 11. Measurement of micro- and macromixing by optical tomography [115]

Higher spatial resolution is required for measurements in regular and irregular packings. Here the distribution of the liquid and the void fraction are investigated as a function of the different packings, the flow rates of the fluids, and the physical properties of the fluids. The distribution of liquid in a trickle-bed reactor has been investigated by using a medical tomograph [121]. Because the energy of this tomograph is rather low, a random packing of glass spheres of diameter 0.4 mm was used in a reactor of 45 mm diameter. The parameter is the liquid flow rate. Because the spatial resolution of the tomograph is on the order of the size of the spheres, the local liquid holdup can be measured, but the paths of the liquid on the spheres cannot be resolved. In similar experimental investigations [122], vertical slices through a packing of 60 mm diameter and 300 mm height were obtained. In more recent investigations, an X-ray tomograph with an acceleration voltage of 120 kV, was used and gave a spatial resolution of about 1.1 mm^2 with a measurement time of 2.5 min [38]. The experimental investigations are carried out in a column of 0.6 m diameter and 2 m height. The packing consists of plastic spheres. The measured liquid holdups show a good agreement with those obtained by an empirical correlation.

3.6. Example of the Application of Tomography in a Trickle-Bed Reactor

A trickle-bed reactor, depicted schematically in Figure 1, consists of a random packing of catalyst spheres. At the top of the reactor, gas and liquid are introduced and flow cocurrently to the bottom. Such reactors are used in the chemical industry for hydrofinishing and hydrocracking. In the packing, four different flow regimes can become established (Figure 12), depending on the flow rates of the fluids. At low flow rates a continuous liquid film flows over the spheres of the packing (Figure 12a). With increasing flow rates the liquid film becomes unstable, eventually forms liquid bridges between the spheres, and the pulse-flow regime (Figure 12b) becomes established. The liquid phase is transported in large plugs through the packing. At high gas flow rates the liquid becomes dispersed and flows in drops through the column (Figure 12c), while at high liquid flow rates the gas phase is dispersed in bubbles. The pulse flow regime is supposed to increase the mass transfer, because of the transient change of gas and liquid phases and the turbulence, and is therefore of major industrial interest.

In the film flow regime, X-ray tomography is applicable, as the time resolution need not necessarily be high. The distribution and the thickness of the liquid films can be measured with high spatial resolution. For the pulse flow regime, high time resolution is essential. The spatial resolution need not to be too high, as the most important parameters to be measured are the location and size of the liquid slugs in the measurement plane, and these are large in comparison to the spheres.

Figure 12. Flow regimes in trickle-bed reactors

Capacitance Tomography. The liquid distribution in the packing for the pulse flow regime has been investigated with the tomographic measurement chain depicted in Figure 13 [15]. It consists of a sensor with 16 electrodes on which electrical microswitches are mounted. These microswitches connect the electrodes with the capacitance meter. With this arrangement only one capacitance meter need be used, and measurement wires are relatively short. The capacitance meter supplies a voltage which is directly proportional to the measured capacitance. This voltage is digitized and stored in a PC for the post-processing of the measurement values. The same PC controls an EPROM, which in turn controls the microswitches attached to the electrodes. The reconstruction can be performed with the backprojection algorithm on the PC or on a workstation, where more sophisticated reconstruction techniques, like ART, are available.

On the left of Figure 14, the sequentially measured pictures are depicted. Regions with a high liquid holdup are shown in dark colors. The ceramic spheres are not visible because they have been removed from the measurement values by calibration of the measurement system. The slices have a time interval of 3 ms and show the change of the phase distribution in the sensor. They can be added to one other to give a quasi-three-dimensional representation of the measurement results. A vertical slice through this extracts the temporal change of the phase distribution in the measurement plane. The liquid plugs which are formed in the reactor are clearly visible in this representation. They have a velocity of about 1.5 m/s and a frequency of about 5 – 10 Hz. The quasi-three-dimensional representation is depicted in Figure 15. Five slices are made through the measurements. The three horizontal slices show the phase distribution as measured by the tomographic system. The larger, vertical slices show the temporal change of the phase distribution.

X-ray Tomography. Figure 16 shows an X-ray tomographic measurement chain. The sensor consists of a X-ray tube which emits radiation in a fan beam. The attenuation of the X-rays in the measurement plane is measured by 15 detectors. The detectors supply a voltage which is directly proportional to the measured attenuation. The voltage is digitized and stored in a computer, which controls the measurement process. The measurement object is mounted on a positioning table, which is turned and shifted to obtain the number of projections needed for the reconstruction. The complete reconstruction is performed on a workstation. The spatial resolution is 0.4 mm^2 at a measurement time of 15 min.

Figure 17 shows the pictures obtained in a trickle bed-reactor with a diameter of 190 mm. The liquid flow rate was $30\,m^3m^{-2}h^{-1}$. Details of the measurement setup and the results are given in [39]. The liquid phase is depicted in black, and the ceramic spheres of diameter 10 mm in gray. From these slices and the slice

Figure 13. Measurement chain for capacitance tomography [15]

Figure 14. Measurement results obtained by capacitance tomography

on the right of Figure 17, it can be seen that the liquid phase is distributed very inhomogeneously in the packing. This is mainly due to the random arrangement of the spheres, which block the flow of the water at some locations, which results in the accumulation of water. To give an impression of the high spatial resolution, Figure 18 shows a three-dimensional representation of the measurement result for ceramic spheres of diameter 10 mm. The figure shows a surface through points in the measurement volume of equal density, which corresponds to the surface of the spheres.

4. Future Perspectives

Capacitance tomography has the advantage of a time resolution which is in the range of 100 slices of the local void fraction per second. The spatial resolution is about 10 % of the sensor diameter and is mainly dependent on reconstruction. The liquid plugs which occur in the pulse-flow regime in trickle-bed reactors, can be measured well. The location and the frequency of the plugs can be identified, and this leads to a better understanding of the formation and the establishment of the pulse-flow regime. Further research in the

Figure 15. Quasi-three-dimensional representation of measurement results

Figure 16. Measurement chain for X-ray tomography

field of capacitance tomography will deal mainly with improving the reconstruction method, decreasing the errors, and therefore increasing the spatial resolution.

With X-ray tomography, a high spatial resolution, on the order of 0.4 mm^2, can be achieved. Because the measurement times are often in the range of minutes, this technique is only applicable to stationary flows. The application of X-ray tomography in the film-flow regime of a trickle-bed reactor shows the uneven distribution of the liquid phase inside the reactor. To decrease the measurement time of these systems, up to now, a considerable technical and monetary effort was

Figure 17. Measurement results obtained by X-ray tomography

Figure 18. Three-dimensional representation of the measurement result for ceramic spheres

necessary. Therefore, these systems are rarely used in research and in process engineering. Further developments will involve shortening the measurement time of such systems without making them more expensive.

1. Water as a Solvent

Hermann Weingärtner

1.1. Properties of Pure Water

1.1.1. *Molecular Properties*

In comparison to other solvents, water and aqueous solutions in many respects show unique properties that are highly sensitive to temperature and pressure [1-3]. These properties result from the structure and the charge distribution of the water molecule. In a simple four-point-charge model, this charge distribution is depicted as a quadrupole with two protons and two lone electron pairs at the corners of a tetrahedron with oxygen in its center (Fig. 1). In the isolated molecule the O–H

internuclear distance is 0.096 nm, with an H–O–H bond angle of 104.3°, which is close to the tetrahedral angle [2], [3]. This nonspherical charge distribution gives rise to electric moments. The dipole moment of the isolated water molecule is 1.85 D (6.14×10^{-30} C · m), the dipole vector acting along the bisector of the H–O–H angle with the negative end directed toward the oxygen. Thus, water is a highly polar solvent.

Figure 1. Four-point-charge model of water after [4]. The partial charges δ^+ refer to the protons, the charges δ^- to the lone electron pairs. The experimental dipole moment is reproduced with $\delta^+ = \delta^- = 0.236\ e$, where e is the elementary charge.

When considering intermolecular interactions, the electrostatic forces have to be supplemented by terms accounting for the core repulsion of the molecules and the attractive dispersion (van der Waals) forces. For water, these terms are often approximated by the corresponding figures for the isoelectronic neon, which has a core radius of 0.14 nm. In computer simulations, models of this type are able to reproduce the major features of the properties of liquid water [4].

1.1.2. *Hydrogen Bonding and Water Structure*

The molecular geometry and charge distribution of water favor the formation of a hydrogen-bonded network with four O–H–O bonds per molecule. Hydrogen bonding can be proved by infrared and Raman spectroscopy. Three normal vibrations of the isolated H_2O molecule occur in the vapor phase: the symmetric stretching mode at a wave number $\bar{\nu}$ = 3675 cm^{-1}, the asymmetric stretching mode at 3756 cm^{-1}, and the bending mode at 1595 cm^{-1} (Fig. 2). Hydrogen bonding leads to shifts in the wave numbers of these modes, a change in their band contours, and the appearance of new bands associated with intermolecular vibrations [3]. These spectral features are often used to monitor changes in hydrogen bonding as a function of temperature and pressure or induced by added solutes. In addition, the chemical shift in the ^1H NMR spectrum of water provides a sensitive tool for measurement of hydrogen bonding.

Figure 2. Normal vibrations of the water molecule: $\bar{\nu}_1$ is the symmetric stretching mode, $\bar{\nu}_3$ the antisymmetric stretching mode, and $\bar{\nu}_2$ the bending mode

The structure of *hexagonal ice* Ih (Fig. 3), which is the stable polymorph of ice at atmospheric pressure, is an ideal representation of this hydrogen-bonded network [3]: Each oxygen is surrounded tetrahedrally by four others at a distance of 0.276 nm, the structure being isomorphous with the tridymite structure of silica. The protons lie approximately along the O–O axes. Because of hydrogen bonding, the intramolecular OH distance (0.101 nm) is greater than in the isolated molecule. If compared with closely packed structures with up to 12 nearest neighbors, the ice Ih structure is very open. The large molar volume of ice Ih is, for example, responsible for the volume contraction of ice upon melting.

Figure 3. Structure of hexagonal ice Ih. The spheres give the positions of the oxygen atoms.

In the *liquid state* the long-range order is lost, but short-range positional and orientational correlations are retained, which can be studied by X-ray and neutron scattering [3]. At room temperature a structure is perceptible in the local environment, which extends to about 0.8 nm. On average, one molecule has 4.4 nearest neighbors at a distance of 0.284 nm. These figures and the location of second-nearest neighbors correspond closely to the requirements imposed by the ice Ih structure. However, intermolecular O–O and O–H distances and H–O–H angles show a broad distribution around the average value, and due to thermal reorientation, the lifetime of a given configuration is only of the order of some picoseconds. With increasing temperature, the three-dimensional network gradually breaks down. Thus, with rising temperature, water loses its unique properties, although Raman spectroscopy shows that even at the critical point at 374 °C, some degree of hydrogen bonding is still retained [5].

Any model of liquid water must accommodate these features, but none of the existing models seems to be immune to criticism. For a long time, so-called mixture models have been used to explain the properties of water and aqueous solutions. These models assume the existence of two (or more) physically distinguishable water species, corresponding to molecules with “broken” and “unbroken” hydrogen bonds [2], [3], according to equilibria of the general form H_2O (icelike) $\rightleftharpoons$ H_2O (gaslike), which depend on temperature and pressure and are changed by solutes. From the present point of view, the need for such models is overcome largely by the possibility of performing more rigorous model-free analyses based on statistical mechanical methods and computer simulations, so that many of these models are only of historical interest.

1.1.3. *Bulk Properties of Liquid Water*

A knowledge of the bulk properties of pure water and their anomalous behavior is a prerequisite for understanding its solvent properties, because many methods and rules for evaluating and predicting data in nonaqueous systems are of little value for aqueous solutions. Most of these anomalies occur near room temperature or up to 100 °C. The significance of these anomalies for processes in nature and in sustaining life has been outlined [3]. Doubtless, these anomalies result from the strong hydrogen bonding that occurs, however, in many other substances as well. Hence, the existence of strong hydrogen bonds cannot fully explain the uniqueness of some properties of water. Rather, it is the existence of the three-dimensional network that distinguishes water from other hydrogen-bonded liquids. Despite great progress in liquid-state theory, the treatment of such hydrogen-bonded systems remains difficult.

Isotopic Composition. Natural ("ordinary") water is a mixture of isotopic species made up by the hydrogen isotopes ^{1}H and ^{2}H (deuterium) and the oxygen isotopes ^{16}O, ^{17}O, and ^{18}O. Their masses and natural abundances are compiled in Table 1. Proton exchange equilibria of the form $^{1}H_2O + {}^{2}H_2O \rightleftharpoons 2\,{}^{1}H{}^{2}HO$ yield further mixed species. The ^{1}H and ^{2}H are usually assumed to be distributed randomly on the oxygens. Then, the four major species of ordinary water occur in the proportions [6]

Table 1. Isotopic masses and natural abundances of hydrogen and oxygen isotopes [11]

	Atomic mass	Natural abundance	
		Mol %	wt %
H (natural)	1.0080		
^{1}H	1.00783	99.985	99.970
^{2}H	2.01410	0.015	0.030
O (natural)	15.9994		
^{16}O	15.9995	99.759	99.732
^{17}O	16.9991	0.037	0.039
^{18}O	17.9992	0.204	0.229

$$^{1}H_2{}^{16}O : {}^{1}H_2{}^{18}O : {}^{1}H_2{}^{17}O : {}^{1}H_2{}^{2}H_2{}^{16}O = 997\,290 : 2000 : 400 : 320$$

The molar mass of ordinary water is 18.012 g/mol. The variation of these proportions in water from different natural sources is usually smaller than variations as a result of water purification, and except in work of the highest accuracy, the properties of ordinary water can be set equal to the properties of $^{1}H_2{}^{16}O$. Practically pure $^{2}H_2O$ (heavy water) and highly enriched ^{17}O- and ^{18}O-labeled water are available commercially, so that some data also exist for water of other isotopic compositions [7]. In the following, the term "water" is used for ordinary water with natural isotopic composition.

p – V – T Data and Invariant Points. Water is the only inorganic substance that, under ambient conditions found in nature, occurs in the solid, liquid, and gaseous states. Its state of aggregation is characterized by the pressure p, the temperature T, and volume V (or density ρ). Only the $p - V - T$ properties of the liquid phase are discussed here. In most applications, the properties of the liquid along the saturation curve can be set equal to the properties at atmospheric pressure.

The *liquid range* is limited by the triple point at which solid ice Ih, liquid water, and steam are in equilibrium and by the critical point. The triple point of ordinary water is bound by the definition of the temperature scale to 273.16 K = 0.01 °C. The normal melting and boiling points at 1.01325 bar are 0 and 100 °C, respectively. The triple-point pressure is $p_t = 6.113\times10^2$ Pa. Recommended values for the *critical temperature, critical pressure*, and *critical density* are [8] t_c = 373.98 °C, p_c = 22.05 MPa, and ρ_c = 322 kg/m^3. Table 2 lists volumetric properties of the liquid from 0 to 100 °C [8], [9]. Here, ρ is the mass density; $\alpha_p = (1/V)(\partial V/\partial T)_p$, the thermal expansion coefficient; and $\chi_T = (1/V)(\partial V/\partial p)_T$, the isothermal compressibility. The thermal pressure coefficient $\gamma_V = (\partial p/\partial T)_V$ can be calculated by $\gamma_V = \alpha_p/\chi_T$.

Table 2. Density ρ, thermal expansion coefficient α_p, and isothermal compressibility χ_T of ordinary water at atmospheric pressure [11]

t, °C	ρ, kg/m^3	$\alpha_p\times10^6$, K^{-1}	χ_T, bar^{-1}
0	999.84	–68.14	50.88

30	995.65	303.1	44.77
	992.23	385.4	44.24

40			
50	988.03	457.8	44.18
60	983.19	523.4	44.51
70	977.76	584.0	45.17
80	971.79	641.3	46.15
90	965.31	696.3	47.43
100	958.36	750.0	49.02

At atmospheric pressure, *ice Ih* contracts by ca. 8.2 % on melting — from a density of 916.8 kg/m^3 to 999.87 kg/m^3 in the liquid. The slope of the melting pressure curve depends on the volume change on melting. The anomalous volume contraction of water leads to a depression of its melting point with rising pressure. This depression continues up to 207 MPa and –22 °C, where the ice polymorph changes to ice II. Close to 0 °C, a pressure of 133 bar is required to lower the melting point by 1 °C.

The volume contraction on melting continues in the liquid phase up to 3.98 °C, where the density reaches a maximum value and the thermal expansion coefficient changes sign from negative to positive. Over the entire temperature range considered, the thermal expansion coefficient of water is one order of magnitude smaller than that of other liquids. The isothermal compressibility is unusually large and possesses a minimum near 46.5 °C. Both extremes represent anomalous properties of pure water that tend to disappear at high pressure.

Actually, liquid water may be supercooled below the equilibrium melting point [10]. Experiments can be performed fairly easily down to –20 °C, which is roughly the limit of heterogeneous nucleation. With special techniques, temperatures as low as –40 °C have been achieved with liquid water. At 1 bar, homogeneous nucleation sets a limit at –43 °C. Many of the anomalous properties of liquid water become even more unusual in the supercooled, metastable regime [10].

Specific Heat. At the normal melting point, the isobaric specific heat c_p increases from 2.072 J K^{-1} g^{-1} in the solid to 4.228 J K^{-1} g^{-1} in the liquid state, where it remains almost unchanged up to 100 °C [8], [9] (a very shallow minimum is found near 35 °C) (Table 3). The specific heat is particularly amenable to molecular interpretation and has often been used to estimate the extent of hydrogen bonding in water [2], [3].

Table 3. Isobaric specific heat c_p, vapor pressure p, latent heat of vaporization $\Delta_l^g h$, and surface tension σ of water at saturation pressure

t, °C	c_p, J g^{-1} K^{-1}	p, bar	$\Delta_l^g h$, kJ/kg	$\sigma \times 10^3$, N/m

Liquid – Vapor Equilibria. The vapor pressure at saturation is given in Table 3 [9]. The slope of the vapor pressure curve yields the latent heat of vaporization $\Delta_l^g h$ [8], [9], which is ca. 2500 kJ/kg at the normal melting point. Up to 100 °C, a slight decrease in $\Delta_l^g h$ is observed (Table 3). Compared with other liquids, the latent heat of vaporization is anomalously high, and its values have often been used to estimate the energy of hydrogen bonds in water. Based on comparison with data for similar molecules, the heat of vaporization of non-hydrogen-bonded H_2O should be ca. 550 kJ/kg, about one-fourth of the actual values between 0 and 100 °C. The difference is ascribed to the energy of the hydrogen bonds.

The vapor pressure is well investigated for other isotopic compositions — above all heavy water. Vapor pressure data for other isotopic forms usually are represented by the partition coefficient $\alpha = p_x / p_{H_2O}$, where H_2O represents light water and x the heavier isotopic form. Figure 4 shows the partition coefficient of heavy water as a function of temperature [7]. Over a

large range of temperature, heavy water is less volatile than light water, so its melting and boiling points (3.82 and 101.42 °C) are higher than those of ^1H_2O. The inverse is true above 200 °C, and the critical point of ^2H_2O is about 3 °C lower.

Figure 4. Partition coefficients α of light (a) and heavy water (b) as a function of temperature

Surface Tension. Below 100 °C, the surface tension σ [8], [9] (Table 3) refers to the interface between water saturated with air and air saturated with water. It is distinctly higher than that of other liquids, including most hydrogen-bonded ones. On the basis of simple theories, the quantity $\sigma/\varrho^{2/3}$ should be a function of the temperature distance $T - T_c$ from the critical point. This is observed approximately, but for water the temperature function of $\sigma/\varrho^{2/3}$ does not exhibit the predicted universal slope found with most other liquids.

Transport Properties. The *dynamic viscosity* η of liquid water (Table 4) is known with great accuracy [6], [8], [9], and the data are often used to calibrate viscometers. The dynamic viscosity is higher than that of comparable substances without hydrogen bonds. The decrease of dynamic viscosity with *increasing temperature* cannot be described with sufficient accuracy by the conventional Arrhenius-type expression with two adjustable constants η_0 and E_η

$$\eta = \eta_0 \exp\left(E_\eta / RT\right)$$

unless the energy of the viscous flow E_η is assumed to be temperature dependent. In other words, the plot of the logarithm of viscosity versus the inverse temperature does not yield a straight line, as found for many other liquids. More complex expressions are therefore in use [10]. The temperature dependence of viscosity is of some interest in interpreting processes in supercooled water [10]. The *pressure dependence* of the dynamic viscosity of water is anomalous as well: Whereas the viscosities of liquids usually increase with increasing pressure, the viscosity of water initially decreases up to a minimum at ca. 60 MPa. This decrease has clear structural implications: the hydrogen-bonded network becomes deformed with rising pressure, and this tends to facilitate molecular motion. An unusually large increase of viscosity (ca. 23 % at 25 °C) is found when ordinary water is replaced by heavy water. At higher temperature, this isotope effect diminishes. This unusually large effect is attributed to a higher structuredness of heavy water.

In gases, the *thermal conductivity* λ is proportional to viscosity, but this correlation is lost in the liquid phase, where for most liquids a linear decrease is found with increasing temperature. In contrast, water shows an anomalous increase in λ up to ca. 130 °C [6], [8], [9] (Table 4). Despite its considerable technical importance, understanding of the thermal conductance of liquids on a molecular basis is poorly developed.

The *self-diffusion coefficient D* characterizes the mean-square displacement of water molecules due to thermal agitation. In ordinary water at 25 °C, $D = 2.30 \times 10^9$ m^2/s [11], corresponding to a displacement of the order of 10^{-4} m during 1 s. The temperature and pressure dependence of *D* and the isotope effects are correlated strongly with those of the reciprocal viscosity.

Autoprotolysis. Self-dissociation of water is characterized by the ion product $K_w = a_{H^+} a_{OH^-}$ or its negative decadic

logarithm. Here a_{H^+} and a_{H^-} are the activities of the H^+ and OH^- ions. At 25 °C, $K_w = 1.008\times10^{-14}$. Accordingly, the pH value of pure water is $pH = -\log a_{H^+} = 7$. The ion product increases with increasing temperature and increasing pressure [12] (see Section Electrolytic Properties). Autoprotolysis is of paramount importance for the Brønsted acid – base concept. According to this scheme, water is classified as an amphiprotic solvent that, depending on the solute, exhibits acidic or basic properties.

Electric Properties. Water exhibits a nonvanishing *electrical conductance*. Values of the specific conductance κ as low as $3\times 10^{-8}\ \Omega^{-1}\ cm^{-1}$ have been achieved, but in practice, water with $\kappa \approx 1\times10^{-6}\ \Omega^{-1}\ cm^{-1}$ is used even in accurate experiments. The discrepancy results from impurities not removable by simple distillation or ion exchange and from dissolved carbon dioxide.

The *dielectric constant* (relative permittivity) ϵ of water (ϵ = 87.81 at 0 °C) is very high and decreases substantially with increasing temperature to 55.44 at 100 °C [13]. The value at 25 °C is 78.46. These high values are attributed to a cooperative alignment of molecules in the hydrogen-bonded network. The dielectric constant is a key quantity for interpreting solute – solvent interactions, above all in electrolyte solutions. Its change with temperature and pressure gives rise to drastic changes in the solvent properties of water.

Other Properties.
Refractive Index. At 25 °C, the refractive index of water is 1.3340. It decreases slightly with increasing temperature.

Standard Enthalpy and Entropy of Formation. The standard enthalpy of formation of water at 25 °C and 1 bar is –286.2 kJ/mol, and the corresponding entropy is 69.98 J $mol^{-1}\ K^{-1}$ [14].

Cryoscopic and Ebullioscopic Constants. The cryoscopic constant K_f = 1.853 g $K^{-1}\ mol^{-1}$ characterizes the freezing-point depression caused by 1 mol dissolved species in 1000 g H_2O. The ebullioscopic constant K_b = 0.515 g $K^{-1}\ mol^{-1}$ characterizes the boiling-point elevation caused by 1 mol dissolved species in 1000 g H_2O.

1.2. Aqueous Solutions

1.2.1. *General Solvent Properties*

At ambient conditions, water is a good solvent for many ionic and polar inorganic and organic substances. To some degree, it can even accommodate nonpolar particles and larger nonpolar molecular groups in the interstitial voids of its hydrogen-bonded network. At high temperature the solvent behavior of water can change drastically. Many comparatively inert substances that mix only poorly with water at room temperature become highly soluble or even completely miscible. In contrast, due to the decreasing dielectric constant, water loses its favorable characteristics as a solvent for ionic compounds.

A useful classification distinguishes among three types of hydration, i.e., ion hydration; hydration of organics with polar functional groups such as OH, C=O, and NH; and “hydrophobic” hydration of inert particles and substances with nonpolar molecular groups. Of these, ion hydration has traditionally received the most interest and is comparatively well characterized. The hydration of substances containing polar functional groups is determined by the extent of solute – solvent hydrogen bonding. In such cases, a highly complex and specific behavior is found. Hydrophobic hydration is a nonspecific “nonbonded” interaction that depends on whether water can build up a stable structure around the inert particle, thereby retaining or strengthening its hydrogen bonds. Hydrophobic effects are therefore determined by the nature of water – water interactions rather than by water – solute interactions, and are driven by a favorable entropy change rather than by energetic contributions. Such processes are very sensitive to temperature, and this strong temperature dependence is one of the essential characteristics of hydrophobic hydration.

1.2.2. *Solutions of Simple Nonpolar Gases*

The solubility of simple low-polarity gases (noble gases, aliphatic hydrocarbons such as methane or ethane, or inert inorganic compounds such as SF_6) in water at 25 °C is lower than in most organic liquids [15] (Fig. 5). Moreover, in contrast to the normal behavior found with other solvents, the solubility decreases as a function of temperature. Only at high temperature (e.g., >100 °C) does the solubility pass through a minimum and then have a positive temperature coefficient like that of normal solvents [16]. Extensive tabulations of gas solubilities in water are available [17].

Figure 5. Solubility of simple gases in water and cyclohexane; x_2 is the mole fraction of the gas (reproduced from [21] by permission)

The thermodynamics of dissolution of inert gases in water and the structural properties of such systems have received wide attention [18], [19], because they are often used to model the hydration of nonpolar groups in more complex molecules. The same interactions play an important role in determining the properties of colloidal and macromolecular solutions, and in the manner in which proteins acquire their native structure [19], [20]. The various properties may be investigated by considering the transfer of 1 mol inert solute from a nonaqueous to an aqueous environment. The latter solutions are nonideal in the sense that the changes in volume and enthalpy on dissolution are negative. However, this is counteracted by a very large negative change of the excess entropy over the entropy of ideal mixing. This dominance of the entropy over the enthalpy term leads to a strongly positive free energy of mixing and, hence, to the low solubility of inert gases in water.

FRANK and EVANS [21] have explained this process by an ordering of water molecules and an increase in the degree of hydrogen bonding around the inert solute. This assumption is supported mainly by the existence of solid hydrates of gases and of other small molecules with definite cage structures (clathrates) [22]. In liquid water, the environment of inert gases and inert molecular groups such as the methyl group are now believed to exhibit some residues of the clathrate structure.

At higher solute concentrations, a second important effect occurs: so-called *hydrophobic interactions* or *hydrophobic bonding* [18-20]. This term denotes the formation of close-encounter configurations between two inert solutes or molecular groups that are stabilized by a favorable common water structure around the pair (Fig. 6). With larger solutes the configuration shown in Figure 6 may, for example, correspond to the encounter of two methyl groups or larger side chains accompanied by a decrease in the number of nearest water molecules. Hydrophobic bonding may include not only configurations with direct solute contact but also configurations in which one layer of water molecules is located between the hydrophobic pair. Since this association process annihilates solute – water contacts, the association is analogous to that expected if an inert solute is removed from an aqueous environment. Thus, the thermodynamic parameters characterizing hydrophobic bonding have signs opposite to those discussed for hydrophobic hydration.

Figure 6. Schematic representation of a hydrophobic association process

A) Two methane molecules form a dimer; B) Stabilization of the conformation of a biopolymer by hydrophobic bonding between two methyl groups or side chains

The spheres represent methyl groups or side chains. The shaded area indicates that the processes occur only in an aqueous environment.

1.2.3. *Solutes with Hydrophilic Groups*

The hydration of polar groups is highly specific, and with molecules carrying both polar groups and inert residues, distinguishing between the various effects is usually difficult. Some insight is often obtained by considering the variation of solution properties within homologous series. Typical examples of such systems include aqueous solutions of alcohols, amines, ketones, ethers, fatty acids, nitriles, or polar gases.

A useful classification that may establish some order in this confusing field is based on the strength and number of proton-accepting groups of the nonaqueous interaction partner [23]. For example, nitriles and ketones are weak proton acceptors, and mixing with water is endothermic. In combination with the entropic term, such solutions are slightly stable thermodynamically and liquid – liquid immiscibilities with upper consolute points are usually found, except for the lowest members of the homologous series. If the solute is capable of accepting stronger hydrogen bonds, the mixing process may become exothermic over some temperature ranges, and a tendency exists for a lower consolute point or a closed miscibility gap. Such behavior is often found with alcohols, ethers, or amines. Finally, in some mixtures, hydrogen bonding is very strong. These are thermodynamically very stable and never separate into two liquid phases. Examples are mixtures with polyhydric alcohols such as glycerol and amides.

Even though knowledge of the hydration of comparatively simple systems is imperfect, the results are of major importance for interpreting the role of water in more complex systems of biological interest. There, hydrophobic hydration and hydrophobic interactions have gained wide attention because these nonbonded interactions play a major role in determining the stability of conformations of biomolecules (e.g., proteins) in solution [19], [20].

1.2.4. *Electrolyte Solutions*

Traditionally, electrolyte solutions have received far more attention than nonelectrolyte systems [24]. The dissolution of a salt in a solvent may be visualized by two steps consisting of (1) dissociation of the salt into gaseous ions and (2) solvation of these ions in the solvent. Consequently, to achieve dissolution, the free energy of solvation must overcome the lattice energy. The polarity and high dielectric constant of water near room temperature favor this process. This, at least qualitatively, explains why the solubility of many salts is higher in water than in nonaqueous solvents. The resulting heats of solution are low, compared to the lattice energies, and in total, the solution process can be exothermic or endothermic.

The dissolution of ions changes the water structure, because the electric field associated with the ionic charge favors definite orientation of the water molecules near the ions. However, other effects also must be accounted for, such as ion – water hydrogen bonds and conditions imposed by the need to form hydrogen bonds with water molecules beyond the first sphere. For anions, most experiments, including neutron-scattering studies [25], give evidence that a hydrogen-bonded configuration in which one of the water protons is directed toward the anion (Fig. 7, right) is preferred to that favored by electrostatic arguments (Fig. 7, left).

Figure 7. Possible configurations of an anion – water pair

With larger univalent ions such as K^+ or I^-, even the water configuration in the first hydration sphere may be quite isotropic. This leads to the *structure-breaking effect*: On dissolution of the salt, water behaves as if its temperature were increased, corresponding to a decrease in the solvent structure. This picture is derived from thermodynamic data such as hydration entropies [21], transport coefficients such as viscosity [24], and spectroscopic data [26], [27]. An illustrative example of the quite unusual effects obtained by the addition of structure-breaking salts is the concentration dependence of viscosity at room temperature. For salts such as potassium iodide, the viscosity decreases with increasing salt concentration, in contrast

to the usual expectations. Salts that follow this pattern are termed structure breakers as opposed to structure formers. This structure-breaking effect exhibited by alkali-metal ions (except Li^+) and halide anions (except F^-) constitutes an anomalous property of aqueous solutions. Multivalent cations and most multivalent anions are *structure formers.*

Because of the high dielectric constant of water near room temperature, most salts of univalent ions are dissociated completely even at high concentration. At high dilution of the salt, the Debye – Hückel theory of electrolyte thermodynamics and its extensions to transport processes provide a correct description of such systems [24]. In the strict sense, these are, however, limiting laws for vanishing salt concentration, as exemplified by the famous Debye – Hückel limiting law for the mean ionic activity coefficient, the logarithm of which exhibits a square-root dependence on salt concentration [24].

Progress in statistical mechanics has also led to an understanding of concentrated electrolyte solutions. Although such theories are notoriously complex, PITZER and coworkers have derived rather simple semiempirical equations for electrolyte thermodynamics that fit, within experimental accuracy, a variety of data on pure and mixed electrolytes in aqueous solutions over wide ranges of salt concentration and temperature [28].

At elevated temperature, where the dielectric constant of water is low, extensive ion pairing may occur [16]. The same is true for electrolytes of higher valence such as sulfates of alkali, alkaline-earth, and transition-metal ions, because the Coulombic interactions between the ions are stronger than in the case of unielectrolytes [24]. In addition, very specific association can be observed, for example, with zinc, cadmium, or mercury halides, where stable complexes are formed [24]. To a certain degree, such ion pairing can be incorporated in PITZER's approach. A more common way, however, is a description in terms of equilibria between distinct ionic species, which are then treated by a simple law of mass action and the corresponding thermodynamic relations [24].

2. Water at High Pressure and Temperature

Ernst Ulrich Franck, Gabriele Wiegand, Nicolaus Dahmen

Water plays a part in many technical processes and is used in a wide range of temperatures and pressures. The critical point above which liquid phase and vapor phase no longer coexist is determined by the critical data t_c = 373.98 °C, p_c = 22.05 MPa, and ρ_c = 322 kg/m^3 (see Section Bulk Properties of Liquid Water).

2.1. Properties of Ice

2.1.1. *Thermodynamic Properties*

Twelve modifications of ice are known [29-31]. The phase diagram of ice in the *p* – *T* projection in the temperature ranges –100 to +600 °C and pressures up to >10^4 MPa is shown in Figure 8 [32], [33]. The densities at 500 °C have also been entered for comparison. Natural ice exists as ice Ih and crystallizes hexagonally. In general, only this modification is of interest for technical processes. A metastable cubic variant of this modification also exists. In Figure 8, ice IV (a metastable modification, which occurs in the phase region of ice V) and ice VIII (with a triple point at ca. 5 °C and 2100 MPa, which is formed from ice VI or ice VII at higher pressure and lower temperature) are not shown. Ice IX and ice XII have also been excluded from Figure 8 because they lie outside the temperature and pressure region depicted in this figure. All known triple points are listed in Table 5 [31], [34].

Table 5 shows that modification II, for example, is not formed directly from liquid water on cooling or compression but can originate only from modifications Ih, III, V, or VI. An anomaly of water is that the melting pressure curve for ice Ih exhibits a negative slope up to the triple point Ih – III – liquid at 207 MPa and –22 °C. The values of the melting pressure curve ice Ih – liquid water are summarized below in tabular form down to this triple point [35]. e

t, °C	*p*, MPa
0.0098	6.1156×10^{-4}
0.0	0.10132
–5.0	59.8
–10.0	110.8
–15.0	155.9
–20.0	193.2
–22.0	207.4

The following equation describes the melting pressure curve of ice Ih in equilibrium with water [36]:

$$\frac{p}{\mathrm{MPa}} = -3.952 \times 10^2 \left[\left(\frac{T/\mathrm{K}}{273.16} \right)^9 - 1 \right]$$

The sublimation pressure curve of ice Ih – water vapor is known down to –110 °C:

t, °C	*p*×10^3, hPa
0	6108

–10	2597
–20	1032
–30	380.1
–50	39.37
–70	2.59
–90	0.093
–110	0.0013

Table 5. Triple points of ice and water modifications

Coexistent phases	Pressure, MPa	Temperature, °C
Ih – liquid – gaseous	6.1×10^{-4}	0.01 *
Ih – liquid – III	207	–22 *
Ih – II – III	200	–30.15 **
Ih – II – VI	1050	–120.15 **
Ih – VI – XII	1550	–168.15 **
II – III – V	350	–21.15 **
II – V – VI	970	–100.15 **
III – liquid – V	346	–17.0 *
V – liquid – VI	626	0.16 *
VI – liquid – VII	2200	81.6 *
VI – VII – VIII	2100	≈5 *

* from [34].
** from [31].

Figure 8. Pressure – temperature phase diagram of water in the solid and liquid states

Densities at 500 °C have been included for comparison.

The heat of fusion of ice Ih – water is 333.69 kJ/kg at 0 °C, and the heat of sublimation of ice Ih – water vapor is 2838 kJ/kg at 0 °C [37], [38].

The molar heat capacity C_p of ice was investigated for ice Ih. Down to –140 °C, the following equation is valid [39]:

$$\frac{C_p(\text{ice Ih})}{\text{J mol}^{-1}\text{K}^{-1}} = 2.369 + 0.130\frac{T}{\text{K}}$$

The parameters of this equation were determined by fitting the data of GIAUQUE and STOUT [35].

T, K	C_p, J mol^{-1} K^{-1}
10	0.276
20	2.050
50	7.931
100	15.879
150	22.025
200	28.211
250	34.829
270	37.481

2.1.2. *Transport Properties*

For the thermal conductivity λ of ice, the following equation is valid in the temperature range 0 to –170 °C [37], [38]:

$$\frac{\lambda}{\mathrm{W\,m^{-1}K^{-1}}} = \frac{488.19}{T/\mathrm{K}} + 0.4685$$

The self-diffusion coefficient *D* is [34]

$$D = 2 \times 10^{-15}\mathrm{m^2/s\,at}\ -7\,^\circ\mathrm{C}$$

2.1.3. *Electrolytic Properties*

Relative Permittivity. The relative permittivity $\in$ was determined on polycrystalline ice at a frequency of ν = 0 Hz:

t, °C	–0.1	–20.9	–44.7	–65.8
$\in$	91.5	97.4	104	133

The relative permittivity increases with decreasing temperature. The phase change from one ice modification to the next-denser one is always accompanied by a jump in $\in$ to considerably higher values along the phase equilibriumcurves with liquid water [32]. Within one modification region, the relative permittivity increases only slightly with pressure. The more densely the water molecules are packed, the higher is the value of $\in$.

The relative permittivity $\in$ depends on the frequency ν of an applied electrical field. This frequency dependence provides information on the rotation of dipole molecules in the lattice. The *dielectric relaxation time* is a measure of how fast the polarization caused by an electrical field decays after the field is turned off. Reorientation times of the water molecules can also be determined by NMR studies [34].

The electrical conductivity κ of ice was determined, e.g., at –10 °C [34], [40]:

$$\kappa = 1.1 \pm 0.5 \times 10^{-10}\Omega^{-1}\mathrm{cm}^{-1}$$

2.1.4. *Mechanical Properties*

The mechanical properties of ice provide information on its stability and load capacity. The mechanical properties of ice Ih are listed below [37], [38]:

Mohs scratch hardness	
at freezing point	≤2
at –78.5 °C	≈6
Tensile strength (–10 °C)	1 – 2 MPa
Compressive strength (–10 °C)	3 – 6 MPa
Young's modulus (–16 °C)	9.42 GPa
Shear strength (–16 °C)	3.55 GPa
Poisson ratio (–16 °C)	0.33 (average)

2.2. Properties of Fluid Water

2.2.1. *Thermodynamic Properties*

For water in the fluid state, equations of state are developed on the basis of experimental *p* – *V* – *T* data and fixed points (e.g., critical data). Exact and sometimes very comprehensive equations of state exist, especially for technical applications [41]. They must sometimes by subdivided for different phase regions. Equations of state that are restricted to parameters interpretable by molecular physics must take into account the high dipole moment of the water molecules and hydrogen bonds between them, especially when the equations apply to moderate temperatures and very high densities [42], [43].

The three-dimensional phase diagram of water is depicted in Figure 9.

Figure 9. Three-dimensional *p* – *V* – *T* phase diagram of water; the coexistence liquid – gaseous region lies in the darkly marked area [44]

C.P. = Critical point

Tabular compilations list *p* – *V* – *T* data up to a maximum pressure of 3000 MPa and maximum temperature of 2000 °C [44-

46]. They are based on International Association for the Properties of Steam (IAPS) recommendations and on the International Formulation Committee (IFC) Formulation for Industrial Use. Selected data for temperature and pressure under saturation conditions are presented in Table 6. Corresponding volumes of the gas and liquid phase along the vapor-pressure curve up to the critical point are included [45]. A comparison between the data listed in the SI steam tables [45] and those compiled in the NBS – NRC steam tables [46] shows that for <300 °C, the values deviate from each other by only ca. 0.1 %. The deviations increase with increasing temperature and can reach 1 %. The enthalpy of vaporization $\Delta_l^g h$ is calculated from the saturation data; it is zero at the critical point. Table 7 shows specific volumes for selected pressures and temperatures in technically relevant regions and also in the supercritical state.

Table 6. Dependence of pressure *p*, specific volume *v* of water (l) and water vapor (g), and enthalpy of vaporization $\Delta_l^g h$ on the temperature in the saturation state at temperatures <100 °C [45]

* The horizontal lines denote the transition between liquid and gaseous state.

Figure 10 shows the specific heat capacity at constant pressure c_p as a function of pressure and temperature. The specific heat capacity at the critical point approaches infinity. In the critical region, the isobars show a pronounced maximum as a function of temperature. For increasing pressures, the maxima become smaller but disappear only above 300 MPa.

Figure 10. Specific heat capacity of water up to 800 °C and 100 MPa; saturated vapor: x = 1, saturated liquid: x = 0 [45]

Values for the isobaric expansion coefficient for temperatures in the range 200 – 1000 °C and pressures between 1 and 100 MPa are listed in Table 8. They pass through a maximum between 300 and 600 °C. The isothermal compressibility χ_T is defined as

$$\chi_T = 1/V(\delta V/\delta p)_T$$

Table 9 shows the dependence of χ_T on temperature and pressure in the pressure range 1 – 100 MPa. The maximum error is $\pm 0.016\times10^{-5}$ MPa^{-1}. The isothermal compressibility and the isobaric expansion coefficient are quantities derived from the $p - V - T$ data.

In the area of technical thermodynamics, the enthalpy – entropy diagram (*h* – *s*) presented in Figure 11 is of interest. It is especially important in the design and operation of power plants.

Figure 11. Enthalpy – entropy diagram of water [44]. *x* = 1: saturated vapor (*x* = 0 would correspond to the saturated liquid)

The velocity of sound *w* in water also depends on pressure and temperature. In the liquid state and at atmospheric pressure (0.1 MPa), it increases with increasing temperature. In the gaseous region and at constant higher pressure (isobaric), the sound velocity passes through a maximum at ca. 100 °C. At constant temperature, the velocity of sound increases with increasing pressure. Values for the sound velocity up to 600 °C and 100 MPa are listed in Table 10 [46].

Table 10. Sound velocity *w* in m/s in water and water vapor up to 600 °C and 100 MPa [46]

* The horizontal lines denote the transition between liquid and gaseous state.

2.2.2. *Transport Properties*

Thermal Conductivity. The thermal conductivity λ of water as a function of pressure and temperature in the range 200 – 800 °C and 10 – 100 MPa is shown in Table 11. Experimental data for higher temperatures and pressures exist: for 250 °C up to 300 MPa [48] and for 250 to 510 °C up to 95 MPa [49]. The values in Figure 12 have been taken from international

tabular compilations [45]. The tolerances are around 1.5 % for 0.1 MPa and 0 °C, but they reach 8 % for 100 MPa and 600 °C. A characteristic feature is that the thermal conductivity of water shows a very pronounced peak at the critical point. This indicates that the change in structure of water is especially great at the critical point. For the supercritical region, the isobars pass through a minimum up to about 50 MPa. This minimum is more pronounced, the lower the pressure. Above ca. 50 MPa, the isobars decrease monotonously without passing through a minimum.

Table 11. Thermal conductivity of water and water vapor (10^{-3} Wm^{-1} K^{-1}) as a function of pressure and temperature in the range 200 – 800 °C and 1 – 100 MPa [45] *

p, MPa	*t*, °C

a) 25 °C; b) 200 °C; c) 400 °C; d) 500 °C; e) 600 °C; f) 700 °C

Dynamic Viscosity. The dynamic viscosity η of water has been studied experimentally in the high-pressure region up to 300 MPa and 500 °C [50]. Figure 13 shows the temperature dependence of dynamic viscosity for various pressures in the sub- and supercritical regions. These data have been taken from SI steam tables [45]. Like other liquids, liquid water has the highest viscosity at low temperature and high pressure (i.e., the region of high density). The viscosity of water decreases rapidly with increasing temperature, even at high pressure. In water vapor, the viscosity increases at low pressure and density with increasing temperature. Between these two limits with, on the one hand, a high and, on the other hand, a low density, a large region exists in which the viscosity of water barely changes (see Section Bulk Properties of Liquid Water).

Figure 13. Dynamic viscosity of water up to 800 °C and 100 MPa [45]

Table 12 shows the viscosity, thermal conductivity, and isothermal compressibility of water [45] along the saturation curve of liquid and vapor in the temperature range 150 – 374 °C.

Table 12. Dynamic viscosity η, thermal conductivity λ, and isothermal compressibility χ_T of water (′) and steam (″) in the saturation state [45]

t, °C	$\eta'\times10^6$, Pa · s	$\eta''\times10^6$, Pa · s	$\lambda'\times10^3$, W K^{-1} m^{-1}	$\lambda''\times10^3$, W K^{-1} m^{-1}	$\chi_T'\times10^3$, MPa^{-1}	$\chi_T''\times10^3$, MPa^{-1}

350	65.88	23.81	447.6	134.6	16.67	215.2
374	43.2		∞		∞	

At the critical point, the thermal conductivity and specific heat capacity extend to infinity.

With increasing temperature, the compressibility increases in liquids but decreases in the gas phase. At the critical point, it approaches infinity.

Self-Diffusion. Very few investigations have been conducted on the diffusion coefficient of water in technically relevant regions of high pressure and temperature [51]. The self-diffusion coefficient as a function of pressure up to 150 MPa and temperature from 25 to 700 °C is shown in Figure 12. In this region, a pressure increase always results in a decrease in the self-diffusion coefficient.

2.2.3. *Electrolytic Properties*

The ion product (see Section Bulk Properties of Liquid Water) has been the subject of diverse studies and discussions. The dependence of the ion product on temperature and pressure is presented in Table 13 [52]. It shows that the logarithmic ion product (e.g., at 400 °C and 100 MPa) assumes a value of approximately 10.8 compared with a value of about 14.0 under normal conditions. The autoionization of water is favored by increasing temperature and increasing density. Thus, an increase in pressure at constant temperature always results in an increase in ion product. Shock-tube experiments have shown that water is ionized completely above 1000 °C and 20 GPa.

Table 13. Ion product –log K_w/(mol kg^{-1})^2 of water up to 1000°C and 1000 MPa [52]

p, MPa	*t*, °C								
	0.0	25.0	100	200	300	400	600	800	1000
p_{Sat}	14.938	13.995	12.265	11.289	11.406

75	14.62	13.73	12.03	10.95	10.66	11.17	15.25	17.35	18.39
100	14.53	13.66	11.96	10.86	10.50	10.77	13.40	15.58	16.72
250	14.08	13.28	11.61	10.45	9.91	9.74	10.18	11.11	12.02
500	13.60	12.83	11.22	10.00	9.34	8.99	8.85	9.11	9.42
1000	12.91	12.21	10.68	9.45	8.71	8.25	7.78	7.68	7.85

For a liquid, water has a very high relative permittivity of ca. 80 under normal conditions because of its unusual structure as a result of the formation of hydrogen bridges (see Section Bulk Properties of Liquid Water).

The relative permittivity ∈ of water and steam up to 500 °C and 500 MPa [53] is given in Table 14. The relative permittivity decreases with increasing temperature (isobaric). If the pressure is increased isothermally (i.e., if density is increased), ∈ increases. In the critical region, the relative permittivity is ca. 6. Pressure and temperature influence not only the value of relative permittivity, but also the solution behavior of water. High relative permittivities favor solubility and ionization of electrolytes.

Table 14. Temperature dependence of the relative permittivity of ∈ water and steam for selected pressures [53]

** The horizontal lines denote the transition between liquid and gaseous state.

2.2.4. *Other Physical Properties*

The interfacial tension σ of water as a function of temperature at the saturation vapor pressure in the temperature range 150 – 374 °C is listed in Table 15. At 20 °C and 0.1 MPa, σ of water reaches a value of 72.75 mN/m, which is very high for liquids. With increasing temperature, the interfacial tension decreases almost linearly until it reaches zero at the critical point [45]. In principle, the isothermal pressure dependence of the interfacial tension of pure water cannot be measured. To generate pressure, the interfacial tension of water must always be measured in relation to a second partner. If gases are used for this purpose (e.g., nitrogen, methane, carbon dioxide, neon, or argon), a decrease in interfacial tension with increasing pressure is observed because the gases dissolve in water and also are adsorbed at the interface. Only at >150 MPa does the interfacial tension increase slightly [54].

Table 15. Surface tension σ of water at 0.1 MPa [45]

t, °C	σ, N/m
150	48.74
200	37.69
250	26.06
300	14.30
350	3.65
374	0

The refractive index *n* of water increases with increasing pressure from 1.334 at 0.1 MPa to 1.347 at 100 MPa.

2.3. Properties of Water Vapor

Most of the physical properties of water vapor have been described in Section Properties of Fluid Water. Its standard enthalpy of formation from the elements at 25 °C and 0.1013 MPa, $\Delta H°_{298.15\ K}$ is 241.99 kJ mol^{-1} K^{-1}; its standard entropy of formation $S°_{298.15\ K}$ is 188.85 J mol^{-1} K^{-1}.

For estimation of *p* – *V* – *T* data at moderate pressure, a virial equation is often used:

$$\frac{pv}{RT} = 1 + \frac{B}{v} + \frac{C}{v^2} + \ldots$$

where *v* is the specific volume in m^3/kg.

The serial development is often stopped after the second virial coefficient *B*. A compilation of values for the second virial coefficient as a function of temperature is given in Table 16 [55].

Table 16. Second virial coefficient of water vapor [55]

t, °C	*B*, 10^6 m^{-3} mol^{-1}	*t*, °C	*B*, 10^6 m^{-3} mol^{-1}	*t*, °C	*B*, 10^6 m^{-3} mol^{-1}
20	–1251.5	200	–206.0	575	–37.5
50	–812.2	275	–132.4	675	–26.2

100	–459.8	375	–82.0	775	–18.1
150	–295.4	475	–54.5	975	–7.6

2.4. Water in the Supercritical State [34], [56], [57]

Above the critical temperature of 374 °C, water possesses many unusual properties at high density. In contrast to the liquid state, for example, mixing with nonpolar gases and many organic compounds with large, nonpolar molecules is generally possible. In addition, supercritical water can dissolve electrolytes with the formation of ions if its density and relative permittivity are sufficiently high. Thermophysical properties such as viscosity and relative permittivity of supercritical water can be changed continuously in wide regions by pressure variation. Thus, water under supercritical conditions can be used as an extraction agent as well as a versatile reaction medium (e.g., for hydrogenation and oxidation). Combinations of pyrolysis, hydrolysis, and oxidation have already been proposed and developed for the emission-free annihilation of pollutants.

3. Water Analysis

Georg Schwedt

3.1. Sampling and Sample Preservation (see also ⟶ Sampling; ⟶ Sample Preparation for Trace Analysis).

Sampling [58-60] is frequently the crucial step in the flawless analysis and evaluation of water. Depending on the type of problem, a distinction must be made between single or random samples and mixed, composite, or average samples (⟶ Sampling – Probability Sampling). In view of representative sampling, the parameters to be considered are very complex. From a homogeneous body of water, a single sample is sufficient to achieve representative sampling. In contrast, in the case of surface waters and stagnant piping systems, several individual samples must be taken. In flowing water, both nonconstant currents and nonhomogeneous water bodies are present. In general, composite samples provide information on certain periods of time, but top loads cannot be discerned. For this reason, the type of sample collection to be used is often stipulated by law to maintain limiting and guideline values. The following DIN processes (no. 38 402) exist for the sampling of unpolluted and polluted waters. Corresponding U.S. processes are found in [60].

Sampling of wastewater	A 11
Stagnant water	A 12
Groundwater aquifers	A 13
Raw water and drinking water	A 14
Flowing water	A 15
Seawater	A 16
Falling, wet precipitation in the liquid state of aggregation	A 17
Water from mineral and medicinal springs	A 18
Water from swimming and bathing pools	A 19
Tidal waters	A 20
Cooling water for industrial use	A 22

Parameter-specific sampling is required, especially in chemical wastewater analysis. Here, too, a legal basis has been established [61], [62]. Further information is contained in ISO standards 5667–1 and -2 (corresponding to EN 25 667–1 and -2) “Water quality sampling: Guidance on the design of sampling programme” and “Guidance on sampling techniques.”

The type and requirements of *sample preservation* [58-60] depend on the constituents to be determined, their concentrations, their possible mutual interactions, and especially the activity of microorganisms contained in the sample. Keeping the sample in darkness and cooling it represent the most general and the most effective processes. For transport to the laboratory, a temperature of 2 – 5 °C is usually sufficient, but for longer storage times, deep freezing at –20 °C is required. Chemical preservation processes depend on the parameters or substances to be determined. A compilation of the preservation processes and techniques for 75 chemical parameters, as well as microbiological examinations, is given in EN ISO 5667–3 (1994, German version 1995).

3.2. Physicochemical and Sum Parameters

In the broadest sense, the term *in situ analysis* refers to analytical methods that can be applied directly to the sample to be investigated for the measurement of physicochemical and sum parameters, or individual components. In this chapter, in situ analyses refer only to processes that must be conducted directly at the sampling site because changes can occur on the way to the laboratory.

In situ analytical processes for water are based mostly on electrometric measuring principles. They include the measurement of temperature, pH, oxygen and redox potential, and conductivity. Moreover, determination of light absorption in the visible and UV regions belongs to the general physicochemical analysis of water samples. A survey is given in Table 17.

Table 17. Physical and physicochemical parameters in water analysis

Parameter	Method	Remarks
Temperature, K (°C)	electronic measurement with temperature probe (DIN 38 404-C 4)	for temperature-dependent quantities: solubility of gases, pH value, electrical conductivity, density
Density, g/cm^3	pycnometer, precision aerometer, bending vibration method (DIN DEV-C 9)	in stronger mineralized waters
Electrical conductivity κ, Ω^{-1} cm^{-1}	conductivity cell with cell constant *K*	measure electrolyte concentration
Conductance *G*, Ω^{-1}	(EN 27888-C 8, ISO 7888)	check *K*, determine temperature coefficient $\alpha_{\theta,25}$
pH value *a* (H_3O^+)	electrometric (potentiometric) measurement with glass electrode and saturated calomel or silver – silver chloride reference electrode (DIN 38 404-C 5)	measure at sampling site because of rapid changes due to physical, chemical, and biological processes: asymmetry balance, correction of electrode slope, consideration of temperature compensation, measurement in low-electrolyte waters with long adjustment times
Redox potential, mV	electrometric (potentiometric) measurement with Pt electrode against reference electrode (DIN 38 404-C 6)	interference by electrode coating and in low-oxygen waters by small changes in concentration of dissolved oxygen
Absorption in visible (436 nm) or UV range (254 nm)	measurement of spectral decadic absorbance *A* (λ), determination of the spectral absorption coefficient (SAC) α (λ) or the specific spectral absorption coefficient (SAC/DOC *) corresponding to α (λ) ρ_{DOC} (436 nm: EN ISO 7887-C 1; 254 nm: DIN 38 404-C 3)	especially a measure of the concentration of aromatics (254 nm); determination of color (436 nm)
Turbidity	by nephelometry: measurement of attenuation of transmitted (860 nm) monochromatic IR light or of scattered radiation (860 nm, scattering angle 90°) (EN 27 027-C 2, ISO 7027)	detection of sand, loam, and clay particles, of bacteria and other microorganisms

* DOC = dissolved organic carbon; see Table 18.

As a result of the large number of substances present in water of various types, *cummulative determinations* have been developed. These provide preliminary information on the degree of pollution or the presence of certain groups of substances. In the narrower sense, *sum parameters* more or less completely identify organic substances after their oxidation to carbon dioxide (Table 18). The *total organic carbon* (TOC) value gives the total content of organic substances, the *permanganate index* detects only easily oxidizable substances, and the amount of biochemically degradable substances is given by the biological oxygen demand (BOD). Determination of parameter ratios provides useful information for water monitoring self-purification processes [58], [63]. For instance, the BOD_5 : COD ratio represents a characteristic value that is specific for wastewater and characterizes its biodegradability. Cumulative determinations such as electrolytic conductivity, residue on evaporation, cation exchange, and pH (Tables 17 and 18) can also be used for *plausibility testing* (e.g., via ion balances) in conjunction with the results of individual determinations. Table 19 shows the differentiation of the sum parameters for haloorganic substances, which also contribute to the characterization of a group of substances. The determination procedure is based on the combustion of a sample at ca. 1000 °C in a stream of oxygen. The combustion products enter an electrolysis cell, and chloride is titrated coulometrically (the sum of all halides is given as chloride value) [64].

Table 18. Chemical and biochemical sum parameters

Parameter	Definition: determination method
Total dry residue ρ_{GT}, mg/L	volume based, mass of dissolved and undissolved (nonvolatile) water constituents (based on unfiltered sample) left after a prescribed drying process (DIN 38 409-H 1)
Filtrate dry residue ρ_{FT}, mg/L	residue on evaporation; volume-based mass of dissolved (nonvolatile) water constituents left after a prescribed filtration and drying process, according to EC drinking water guideline at 180 °C (DIN 38 409-H 1: 105 ± 2 °C)
Substances removable by	according to DIN 38 409-H 2

filtration P_A, mg/L	
Residue on ignition P_{GA}, mg/L	ignition (550 °C) of the filtrate dry residue (DIN 38 409-H 2)
Cumulative determination by cation exchange, mmol/L	exchange of cations by oxonium ions
Total hardness, degrees of hardness [e.g., d GH [b] or as d (Ca^{2+} + Mg^{2+})], mmol/L	EDTA-Na_2 [a] and Eriochrome Black T (pH 10) (DIN 38 406-E 3–3) or by AAS [c]: DIN 38 406-E 3–1 or ISO 7980
Acid and base capacity ($K_{A,4.3}$, $K_{A,8.2}$ and $K_{B,4.3}$, $K_{B,8.2}$), mmol/L	neutralization titration with HCl or NaOH against methyl orange or phenolphthalein or with electrometric end point indication (pH 4.3 or 8.2)
Calcuable therefrom: *m* and *p* alkalinity, mmol/L [d]	*acid capacity*: volume-based quantity of hydronium ions that a sample can absorb until it reaches a certain pH; *base capacity*: volume-based quantity of hydroxyl ions that a sample can absorb until it reaches a certain pH. An aqueous CO_2 solution with a HCO_3^- ion concentration (mmol/L) of 1 % of the concentration of dissolved CO_2, a temperature of 25 °C, and an ion strength of 10 mmol/L has a pH of 4.3. An aqueous HCO_3^- solution with >1 mol/L HCO_3^- ions, a temperature of 25 °C and an ionic strength of 10 mmol/L has a pH of 8.2. Details in DIN 38 409-H 7. Acid and base capacity are determined for the calculation of $c(CO_2)$, $c(HCO_3^-)$, and $c(CO_3^{2-})$. Influenced by the presence of other weak acids
TIC, mg/L (calculated as C)	total inorganic carbon to be derived from the carbon sum $TIC = c(CO_2 + c(HCO_3^-) + c(CO_3^{2-})$, which is determinable for Q_C > 0.5 mmol/L, according to TIC = *m* alkalinity – *p* alkalinity (DEV D 8); or determination in the course of TOC determination [d]
TOC, mg/L (calculated as C)	total organic carbon determination by oxidation of all C compounds to CO_2 (UV irradiation in the presence of an oxidant such as peroxodisulfate at ca. 60 °C (measurement of CO_2 by IR spectrometry, coulometry, or conductometry, or after reduction to methane by GC/TCD [e] or FID [f]) (DIN 38 409-H 3)
DOC, mg/L (calculated as C)	dissolved organic carbon (mostly after membrane filtration – 0.45 µm pore size)
POC, mg/L (calculated as C)	particulate (undissolved) organic carbon
VOC, mg/L (calculated as C)	volatile organic carbon
Permanganate index, mg/L	mass per unit volume of oxygen that is equivalent to the mass per unit volume of consumed permanganate ions (permanganometric, detects easily oxidizable substances) (DIN 38 409-H 5, ISO 8467)
COD, mg/L	determination of oxidizability with potassium dichromate, volumetrically or photometrically (at 340, 445, or 585 nm) (DIN 38 409-H, ISO 6060)
BOD, mg/L	determination of the volume-based mass of oxygen that is consumed for oxidation of the biochemically oxidizable constituents contained in a 1-L water sample in *n* days (generally *n* = 5, BOD_5) with the metabolic activity of a corresponding microbiocenosis at 20 °C (DIN 4045; DIN 38 409-H 51, ISO 5815); oxygen determinations volumetrically, manometrically, or electrometrically with oxygen electrode

[a] Ethylenediaminetetraacetic acid disodium salt.
[b] GH = Gesamthärte (total hardness).
[c] Atomic absorption spectrometry.
[d] For definition of *m* and *p* alkalinity see Section Characterization of the Chemical State of Water.
[e] TCD = thermal conductivity detector.
[f] FID = flame ionization detector.

Table 19. Differentiation of sum parameters for haloorganic compounds (parameters in µg/L, calculated as Cl)

Parameter	Detectable substances

TOX	total halogens in organic compounds (total organic halogens)
DOX	dissolved organic halogens
AOX	adsorbable (mostly on activated carbon) organic halogens
POX	purgeable organic halogens (DEV H 25)
VOX	volatile organic halogens
EOX	extractable organic halogens
TOCl	total of organic chlorine
DOCl	dissolved organic chlorine

Most of the processes mentioned also exist in a variant for on-line analysis. Equipment for on-line analysis allows the course of processes in the waste treatment plant to be controlled with robust (i.e., often also no- or low-maintenance) measuring devices.

3.3. Inorganic Analysis

The analytical procedures for inorganic cations and anions range from simple analytical colorimetric testing methods in the field, spectrophotometry, electrochemical methods (especially polarography and inverse voltammetry), and ion chromatography (IC) to atomic absorption spectrometry (AAS), optical atomic emission spectrometry with inductively coupled plasma (ICP – OES), as well as inductively coupled plasma coupled with high-resolution mass spectrometry (ICP – MS) [65], [66].

3.3.1. *Determination of Cations*

Because of the efficiency of instrumental methods, cation analysis is carried out mostly in water without any special sample preparation. However, trace enrichment processes [67], [68] or digestion (usually UV digestion for the destruction of organic substances) must be applied in the case of less selective methods, such as spectrophotometry, or because of interference by organic substances. [Trace enrichment is conducted with simultaneous matrix separation on selective ion exchangers and, after chelation with complexing agents such as dithiocarbamates, on chemically modified silica gel or polymer adsorbents or on activated carbon, which can also be used as flow injection analysis (FIA) technique.] A survey of the generally accepted analytical methods and of the cations that can be analyzed is presented in Table 20. The analytical methods standardized for water analysis are collected in the “German Standard Methods for the Examination of Water, Wastewater, and Sludge” (Deutsche Einheitsverfahren zur Wasser-, Abwasser- und Schlammuntersuchung, DEV).

Table 20. Methods of cation analysis

Method	Determinable cations
Spectrophotometry (with selective reagents, partly as FIA-technique), colorimetrically as quick test	Al, Ag, As. Cd, Co, Cr(III, VI), Cu, Fe, Hg, K, Mn, Ni, Pb, Zn
Fluorescence spectrometry (with selective reagents)	Al, Be, U
Atomic absorption spectrometry (AAS), flame or graphite tube technique	
Digestion/extraction with dithiocarbamate (DIN 38 406-E 21)	Ag, Bi, Cd, Co, Cu, Ni, Pb, Tl, Zn
Hydride AAS-technique	As, Bi, Ge, Pb, Sb, Se, Sn, Te
Cold vapor technique (DEV-E 12)	Hg
Atomic emission spectrometry with inductively coupled plasma (ICP – OES) (DIN 38 406-E 22)	Ag, Al, As, B, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, K, Li, Mg, Mn, Mo, Na, Ni, P, Pb, S, Sb, Se, Si, Sn, Sr, Ti, V, W, Zn, Zr
ICP mass spectrometry (ICP – MS)	Ag, Al, As, B, Ba, Bi, Ca, Cd, Co, Cr, Cs, Fe, Hg, K, Li, Mg, Mn, Mo, Na, P, Pb, Rb, S, Sb, Se, Sn, Sr, Th, Ti, Tl, U, V, W, Zn
Polarography and voltammetry (DIN 38 406-E 16)	Cd, Co, Cu, Ni, Pb, Tl, Zn
Potentiometric stripping analysis	Ag, As, Bi, Cd, Co, Cu, Fe, Hg, In, Mn, Ni, Pb, Sb, Se, Sn, Tl, U, Zn

Apart from classical spectrophotometry (and fluorescence spectrometry for a few elements), high-performance methods of atomic spectrometry are available today. These include atomic absorption spectrometry with flame AAS (⟶ Atomic Spectroscopy – Flame Atomic Absorption), graphite furnace technique (flameless AAS; ⟶ Atomic Spectroscopy – Electrothermal Atomic Absorption), the hydride technique (for elements that form volatile hydrides), the cold vapor technique (for Hg, ⟶ Atomic Spectroscopy – Hydride and Cold Vapor Techniques, and as a multielement determination method,

optical emission spectrometry with inductively coupled plasma as the excitation source (⟶ Atomic Spectroscopy – Inductively Coupled Plasmas). The latter can be coupled with high-resolution mass spectrometry (ICP – MS technique) to achieve still lower detection limits and larger linearity ranges and to measure the abundance ratios of isotopes [69]. Despite the advances in and efficiencies of these methods, matrix effects and interference still must be taken into account. They must often be eliminated by special sample preparation, such as selective extraction or concentration. In addition, electrochemical methods such as polarography and voltammetry [70], especially the stripping technique — after concentration on the electrode — (⟶ Analytical Voltammetry and Polarography – Stripping Voltammetry.) and potentiometric stripping analysis (PSA, ⟶ Analytical Voltammetry and Polarography – Stripping Chronopotentiometry (SCP).), are important in water analysis. In PSA, metal ions capable of amalgam formation are first deposited on a working (usually glassy carbon) electrode by potentiostatic electrolysis. The metals are then oxidized and again dissolved (stripped), the time required being proportional to their concentration in solution. The potential – time curves are evaluated.

In cation analysis, besides determination of total concentrations, element species analysis (*speciation*), i.e., differential analysis of one element according to different chemical bonding and physical form of state, is becoming more and more important [71]. Examples are the determination of chromium as Cr(III) and Cr(VI) [72], arsenic as As(III) and As(V) [73], and inorganic and organic tin compounds [74]. For speciation, coupling processes with a chromatographic separation system (gas and liquid chromatography) and atomic spectrometric detection have gained importance [75].

3.3.2. *Anion Analysis*

Spectrophotometry is the classical analytical method in anion analyis, as well. For some elements present in the anionic state in water (e.g., B, V, Mo), methods of cation analysis are also used (Table 20). In addition, for some special anions such as fluoride, nitrate, and cyanide or sulfide, *ion-selective electrodes* [76] have proved useful in direct potentiometric determination (with use of the standard addition process and integrated in FIA systems for calibration). Most of the processes can be automated; i.e., they can also be employed as FIA systems (Table 21). Furthermore, special problems such as determination of the total nitrogen or total phosphorus concentration in wastewater samples can also be solved by using the FIA technique [77], [78]. In these processes, digestion of all nitrogen compounds (oxidation under UV radiation with peroxidisulfate) to nitrate or of organic phosphorus compounds to orthophosphate (by acid and microwave radiation) is integrated into the flow system.

Table 21. Methods of anion analysis

Method	Determinable anions
Spectrophotometry (after chemical conversions with selective reagents)	borate, chromate, cyanide, fluoride, iodide, nitrate, nitrite, phosphate, silicate, sulfate, sulfide, sulfite, thiocyanate (others such as borate/B, molybdate/Mo, vanadate/V; see also cation analysis in Table 20)
Potentiometry with ion-selective electrodes	fluoride, cyanide, nitrate
Ion chromatography	
(DIN 38 405-D 19) in slightly polluted water	fluoride, chloride, nitrite, phosphate, bromide, nitrate, sulfate
(DIN 38 405-D 20) in wastewater	chloride, nitrite, phosphate, bromide, nitrate, sulfate
(DIN 38 405-D 22)	chromate, iodide, sulfite, thiocyanate, thiosulfate

Since the early 1980s, *ion chromatography* has been of utmost importance in anion analysis [79]. Being a type of high-performance liquid chromatography, it uses separation columns with anion exchangers on a polymer or silica gel basis, as well as ion-pair separation systems in conjunction with different detection methods such as conductivity, UV, and amperometric detection [59]. If solutions with carbonate – hydrogencarbonate as eluting ions are employed, the suppressor technique for neutralization of the mobile phase (by means of an ion-exchange membrane in the H^+ form) is used in conjunction with conductivity detection. Ions that absorb UV, such as nitrate, nitrite, bromide, iodide, or thiocyanate, can be detected directly (by using UV transparent eluents); ions that do not absorb UV can be detected by indirect UV detection (UV-adsorbing eluent such as phthalate buffer or complexons [80]); and electrochemically active (oxidizable) anions, such as iodide and nitrite, can also be detected amperometrically [81]. This wide range of separation and detection methods is a characteristic feature of ion chromatography. In anion analysis, the latest method is capillary electrophoresis in the form of *zone electrophoresis* [82].

3.3.3. *Determination of Dissolved Gases*

The most frequently determined dissolved gases in water are oxygen, ozone, carbon dioxide, and chlorine.

Oxygen. The classical *Winkler process* for the measurement of oxygen is based on the conversion of manganese(II) to manganese(IV) hydroxide under alkaline conditions (“oxygen fixation”), with subsequent iodimetric determination (EN 25 813, ISO 5813). Measurements with an *oxygen electrode* (as oxygen sensor) according to Clark, are based on the following principle. In an electrolyte-filled reaction chamber, a gold cathode and a silver electrode, which is involved in the redox processes and acts as the anode, are polarized with a direct voltage of 790 ± 10 mV. The reaction chamber is sealed with a gas-permeable membrane. Oxygen from a water sample reaches the cathode by diffusion [e.g., via a teflon (polytetrafluoroethylene) film] and is reduced. Silver dissolves correspondingly at the anode. The current flowing in the cell is

proportional to the partial pressure of oxygen [58].

Carbon Dioxide (see Section Characterization of the Chemical State of Water). The carbon dioxide content ("free carbonic acid") can be calculated from the total inorganic carbon (TIC = *m* alkalinity — *p* alkalinity), with the *m* and *p* alkalinities (see Section Physicochemical and Sum Parameters) determined by titration taking the pH and conductivity into account (in the pH range 6.0 – 8.4) [58]. Carbon dioxide can also be measured with the aid of a *gas-sensitive electrode*. In the case of a CO_2 electrode, as with the oxygen sensor, gas molecules diffuse through a semipermeable membrane into an electrolyte solution (hydrogencarbonate). On entry of CO_2, the pH of this hydrogencarbonate solution is shifted, corresponding to the equilibrium between carbon dioxide and hydrogencarbonate. The pH shift is measured. The standard processes DEV-D8 [calculation of dissolved carbon dioxde (free carbonic acid), carbonate, and hydrogencarbonate ions] and DIN 38 404-C 10 (calcium carbonate saturation of a water sample) are available for investigations of the carbonate balance including the calcium carbonate system that are important in practice.

Chlorine. For the determination of *free chlorine* and *total chlorine* (e.g., in swimming pool water), both chemical and physicochemical processes (using an electrode) are available. The photometric or colorimetric (also possible volumetrical) process (DIN 38 408-G 4) is based on the reaction of elemental chlorine (as well as hypochlorous acid and hypochlorite ions, where the sum = free chlorine) with *N,N*-diethyl-*p*-phenylenediamine to give a red oxidation product. Chloramines can be detected only after conversion with iodide (bound chlorine). The content of chlorine can also be determined with a *gas-sensitive electrode* (measurement of redox potential).

Ozone. Like free chlorine, ozone is determined photometrically.

3.3.4. *Quick Test Processes*

For most of the parameters described in Sections Anion Analysis and Determination of Dissolved Gases, chemical quick tests — also called alternative tests compared to laboratory processes — are available on the market. They include test papers (for "semiquantitative" analysis of various metal ions), test strips, colorimetric tests, and gas testing tubes for substances that can be purged out of water [83].

As an analysis involving carrier-bound reagents, *test strips* are square reaction zones made of paper applied to plastic strips. With the help of a pocket instrument, test strips can also be evaluated by reflectometry.

The application of *gas testing tubes* has been extended from workplace monitoring to include water analysis. In water analysis, volatile substances are purged out of water with the help of air and a gas-washing bottle. A certain volume of air is sucked through the testing tube (located between gas-washing bottle and pump) by using a bellows pump. The length of the colored zone is a measure of a definite concentraton of the gas to be determined.

Colorimetric quick tests are available in the form of cuvette tests with color comparison, as a rotary-disk comparator, or a color-scale sliding comparator. If two cuvettes are used — one cuvette for the untreated sample — the self-color of a water sample can be compensated for. Visual colorimetry according to the Lambert – Beer law based on the principle of remission measurement (in a direct-light process) with greater layer depths (compared to the rotary-disk comparator) and higher sensitivity finds application in color chart tests. The color of a sample of water after the addition of reagents is compared with the colors on a plastic color chart valid for one concentration range in each case (lower and upper limits). The reagent sets used in these processes can also be applied in photometric determinations for on-the-spot analysis with the help of battery-driven pocket photometers.

3.4. Organic Analysis

The analysis of organic substances in water is characterized on the one hand by cumulative detection on the basis of sum parameters (see Section Physicochemical and Sum Parameters) and by biochemical and biological test methods (see Section Biochemical Methods) for total effect-oriented analysis. On the other hand, analysis of individual substances is carried out by using efficient chromatographic separation methods [84]. The groups of substances most often analyzed are pesticides, polycyclic aromatic hydrocarbons, haloorganic hydrocarbons, phenols, hydrocarbons from mineral oils and mineral oil products, and surfactants.

3.4.1. *Spectrometric Methods*

Unlike the analysis of inorganic water constituents, UV - visible (UV – VIS) spectrometry plays a much smaller role for organic substances. Substances determined by UV – VIS spectrometry include, e.g., uric acid and pyridine as single substances; phenols (phenol index DIN 38 409 H 16), organic complexing agents such as ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA), and phosphonic acids (as bismuth complexation index I_{BIK}; humic acids; lignosulfonic acids [85]; and surfactants (DIN 38 409 H 20 and 23) as groups of substances.

For turbid water, *derivative spectrometry* is the method of choice not only to eliminate the interference of colloids and particles, but also to obtain characteristic spectra ("shoulders" of the original spectrum give minima in the first derivation), e.g., in the determination of phenol [59].

Fluorescence spectrometry (⟶ Ultraviolet and Visible Spectroscopy – Fluorimetry is based on the property of substances absorbing energy (excitation) in the form of light (UV – VIS range) and emitting it as radiation with lower energy, i.e., longer wavelength (fluorescence). Fluorimetry is most important as a detection method in conjunction with separation methods. It is also used to determine the concentration of chlorophyll A (DIN 38 412 L 33) in algae in the examination of the trophic state of waters; in the qualitative analysis of polycyclic aromatic hydrocarbons (PAHs); in surfactant analysis; and in the characterization of humic substances. Humic substances are characterized spectroscopically [86] by spectral absorption coefficients at 245 and 436 nm and by fluorescene with an excitation wavelength of 330 (or 341) nm and fluorescence radiation of 410 (or 460) nm. Complexable paramagnetic metal ions quench this fluorescence.

Infrared spectroscopy is based on the absorption of electromagnetic radiation for the initiation of mechanical vibrations of atoms or functional groups in a molecule. This method is used primarily in the characterization and quantification of hydrocarbons. Sample preparation involves extraction with CCl_4 or 1,1,2-trichloro-trifluoroethane (DIN 38 409 H 18). Nonhydrocarbons (such as surfactants) that are also extracted in this process are separated on a polar adsorbent. The characteristic absorption bands used are 3.38 µm ($\tilde{\nu}$ = 2958 cm^{-1}) for the CH_3 group, 3.42 µm ($\tilde{\nu}$ = 2924 cm^{-1}) for the CH_2 group, and 3.30 µm ($\tilde{\nu}$ = 3030 cm^{-1}) for the aromatic CH group (⟶ Infrared and Raman Spectroscopy – The Concept of Group Frequencies, ⟶ Infrared and Raman Spectroscopy – Methyl and Methylene Groups, ⟶ Infrared and Raman Spectroscopy – Alkene Groups, ⟶ Infrared and Raman Spectroscopy – Aromatic Rings). Humic substances and surfactants [87] can also be characterized by IR spectroscopy.

3.4.2. *Gas and Liquid Chromatography*

As physicochemical separation methods, chromatographic methods [84] based on the distribution of substances between a stationary and a mobile phase in conjunction with various detectors play an important role in qualitative and quantitative analysis, especially of organic substances (see also ion chromatography, Section Anion Analysis). *Gas chromatography* with a gas as the mobile phase is especially suitable for volatile substances (i.e., substances that evaporate without decomposition). The stationary phase consists of a solid (adsorbent) or fluid. The highest separation efficiencies are attained in capillary columns. Liquid chromatography with a liquid mobile phase is conducted as *thin layer (planar) chromatography* (TLC) or as *high-performance liquid chromatography* (HPLC) in columns (with small particles of 3 – 10 µm diameter as separating materials (for details, see [84]).

Gas Chromatography. In general, sample preparations are required for gas chromatography. These preparations involve direct transfer of the substances to be analyzed from the water sample to the separation column or first to an organic (easily evaporable) solvent. *Headspace analysis* (⟶ Gas Chromatography – Static and Dynamic Head Space Analysis) is used for volatile organic water constituents such as halogenated hydrocarbons [88], [89]. The sample of water is heated to a given temperature in a headspace sample vial provided with a silicone membrane and rubber seal. A controllable equilibrium is established between the liquid and the gaseous phase. With a gastight syringe, a defined volume can be withdrawn from the headspace via the silicone membrane and rubber seal of the sample vial and used for GC analysis without the interfering matrix water. In the *purge-and-trap process*, a highly pure stream of helium gas is first passed through the water sample. The highly volatile organic compounds enter the helium gas phase (purge process) and are then retained and concentrated in an adsorption tube (with an adsorbent such as tenax, i.e., a linear polymer of *para*-2,6-diphenylphenylene oxide; trap process). The substances are desorbed by rapid heating (thermal desorption) and then transferred directly to the sample inlet of a gas chromatograph (⟶ Gas Chromatography – Thermal Desorption Units). Other sample preparation processes for GC analysis are liquid – liquid (e.g., with *n*-pentane) and solid – liquid extraction (concentration and separation from water on adsorbents made of chemically modified silica gels with functional groups such as *n*-alkyl, usually C_{18}, phenyl, aminopropyl etc.). Microextraction is also possible [90], [91]. The efficiency of a GC analysis system is determined not only by the separation column but also by the type of detector used. For relevant water constituents, a compilation of GC processes with the detector used in each case is presented in Table 22 (examples: pesticides [92], polychlorinated biphenyls [93], coupling with a mass selective detector [94], and mass spectrometry [88]).

Table 22. Applications of GC analysis

Group of substances	GC process or detector (DIN)
Halogenated hydrocarbons with low volatility	electron capture detector (ECD) (DIN 38 407-F 2)
Highly volatile halogenated hydrocarbons	
After extraction with, e.g., *n*-pentane or *n*-hexane	ECD (DIN 38 407-F 4)
Headspace analysis	ECD (DIN 38 407-F 5)
Phenoxyalkane carboxylic acids with liquid – liquid extraction and derivatization	mass spectrometric detector (MSD) (DIN 38 407-F 14)
Phenols (selected) after derivatization	ECD (DIN 38 407-F 15)
Aliphatic hydrocarbons	flame ionization detector (FID)
Organic solvents	FID
Selected organic nitrogen and phosphorus compounds (pesticides) after concentration by solid-phase extraction	phosphorus – nitrogen detector (PND) (DIN 38 407-F 6) combination of GC and mass spectrometer
Aromatic hydrocarbons	photoionization detector (PID)
Hydrocarbons	combination of GC and FTIR (Fourier transform infrared spectrometry)
Benzene, toluenes, xylenes (BTX)	FID (DIN 38 407-F 9)
Vinyl chloride	ECD (DIN 38 413-P 2)
Polychlorinated biphenyls (PCBs)	ECD

Thin layer chromatography is widely applied, especially in the analysis of polycyclic aromatic hydrocarbons. For this purpose, one-dimensional or two-dimensional separation is conducted after extraction with chloroform in accordance with

DIN 38 409-H 13. This analysis is limited to six representative PAHs. Quantitative evaluations can be achieved by means of a thin layer scanner via UV absorption or fluorescence measurement.

Automated multiple development (AMD) is used as a special development technique in the separation of selected organic pesticides (DIN 38 407-F 11). This is a modern technique for stepwise development, which — unlike the classical process — starts with the solvent having the highest polarity and ends with the solvent having the lowest elution strength. Development is carried out in a vertical chamber using high-performance (HP) TLC plates. It is started with a run of 8 mm and is continued up to 25 times with a 3-mm run each time. After each step, the solvent is removed from the chamber by suction, and each step is preceded by layer conditioning. The AMD technique with the important effect of spot focusing is one of the most efficient developments in TLC.

High-Performance Liquid Chromatography. In comparison with GC and TLC, HPLC has the advantage that aqueous phases can be used on reversed-phase materials (silica gels with *n*-alkyl groups such as C_{18}, RP-18, ⟶ Liquid Chromatography). Thus, extraction of the substances to be analyzed from water samples and transfer to an organic phase are usually not required. Concentration can also be conducted in a precolumn directly before the separation column. Another advantage (especially over TLC) is the large selection of different types of detectors (UV – VIS detectors with fixed or variable wavelengths or diode array systems for the detection of spectra; and fluorescence, amperometric, and conductivity detectors) and the possibility of coupling with mass spectrometry [95]. The level of instrument technology makes a high degree of automation possible — starting with sample application, precolumn concentrations, gradient elution (e.g., increasing methanol concentration in a water — methanol eluent mixture), and recording of spectra, and ending with evaluation. In water analysis, this gradient elution is applied mainly to separation of pesticides (DIN 38 407-F 12) [96] and polycyclic aromatic hydrocarbons (ISO 7981–1, DEV process F 8) [97].

3.5. Biochemical Methods

Biochemical and biological testing methods [98] are used to test the effects of chemical and physical parameters, i.e., especially of substances dissolved (present) in water, on enzymes (biochemical) or on certain test (water) organisms. The term " effects" refers not only to the acute and chronic toxicity of individual substances, but also to detrimental biological effects in general caused by all the noxious agents together (i.e., total noxiousness). Synergistic and antagonistic effects are also discerned. Although the qualitative and quantitative identification of single substances is possible in chemical and physicochemical analyses (Sections Sampling and Sample Preservation , Physicochemical and Sum Parameters, Inorganic Analysis, Organic Analysis), no information can be provided on the joint action of several potentially toxic substances. If a damaging effect is determined in the proceses described below, the substances responsible must be identified by chemical analysis. Thus, biochemical and biological test methods are of significance as a precursor to instrumental analysis. They represent an important preliminary test and supplement the analytical determination of substance concentrations.

The enzymatic and biochemical processes employed include enzyme inhibition tests and enzyme-coupled immunochemical tests, i.e., enzyme-linked immunosorbent assays (ELISA; ⟶). ELISA tests use the ability of organisms to form antibodies against foreign higher-molecular mass substances and to bind the foreign substances with these antibodies. By coupling environmentally relevant low-molecular mass substances to larger proteins, antibodies are produced that respond specifically to these low molecular substances (haptens) [99]. The antibodies obtained are immobilized on the inner wall of plastic tubes (or in the cavities of microtiter plates) for an antigen – antibody reaction. The water sample and an enzyme conjugate, which consists of the analyte coupled with an enzyme, are then placed in a tube of this type. The free analyte molecules in the sample and the analyte molecules bound to the enzyme compete for the free binding sites on the immobilized antibodies. After a rinsing step, a solution containing the enzyme substrate is added. A dye is produced as a result of the enzymatic reaction. The higher the intensity of the color, which can be measured photometrically, the lower is the concentration of analyte molecules in the sample. The ELISA tests are available for a series of pollutants, especially for herbicides such as alachlor, cyanazine, atrazine, 2,4-dichlorophenoxyacetic acid, and metolachlor; for insecticides such as aldicarb, carbofuran, and chlorodienes, such as chlorodane, aldrin, dieldrin, heptachlor, endrin, and endosulfan; for benomyl, metalaxyl, and the fungicide captan; and also for PAH and polychlorinated biphenyls (PCBs).

Enzyme Inhibition Tests. Of the enzyme inhibition tests, the acetylcholinesterase inhibition test for phosphate esters, phosphate thioesters, and methyl carbamate is of special interest ⟶ Enzyme and Immunoassays – Enzyme Assays: Determination of Inhibitors) [100]. In this test, enzyme activity is inhibited by substances that act as neurotoxins. The inhibitory effect can be determined photometrically on the basis of the substrate reaction (e.g., with thiocholine). A *biosensor* is produced by combining an enzyme immobilized on a membrane with a pH (flat-bed) electrode [101]. The substrate reaction can then be determined from potential measurements. For the analysis of a drinking water sample, the activity of the enzyme membrane of the electrode is determined by dipping the membrane into a substrate-containing (acetylcholine) solution. As a result of enzymatic hydrolysis, acetic acid is released in the enzyme membrane. The resulting shift in pH is measured by a pH electrode and is a measure of the enzyme activity. After incubation in an inhibitor-containing sample of drinking water, the active center of the enzyme is blocked irreversibly, e.g., by phosphate ester molecules. Consequently, the activity of the enzyme is reduced. Subsequent determination of activity with the same substrate solution as before shows a lower activity. In this manner, detection limits of 0.1 µg/L can be achieved under optimum incubation conditions without previous analyte enrichment.

Biological Tests. Of the biological tests, the luminescent bacteria test DIN 38 412-L 34 and L 341) [102] is widely applied because it is easy to handle. A NaCl solution is added to the deep frozen test charges to give a temperature of 15 °C, and the bioluminescence (as a part of the bacterial metabolism) is measured. After addition of a wastewater sample and an incubation time of 30 min, the luminescence is measured again. The decrease in luminescence is a measure of bacterial toxicity. For wastewater analysis, dilution series are made to determine the dilution for an inhibition of 20 % by means of interpolation.

The reviews "Water Analysis" in the journal *Analytical Chemistry* survey the developments in methods and analyses over a period of two years [103].

4. Hydrological Cycle and Water Use

Fritz H. Frimmel and Birgit C. Gordalla

4.1. World Water Balance

The appearance of the earth is characterized by the natural occurrence and physical properties of water. As the basis of all life, water is an essential component of nature. Although the total global water volume of 1.38×10^9 km^3 accounts for only about 0.23 ppm of the mass of the earth, it covers 71 % of the earth's surface. The distribution of water among different regions of occurrence is shown in Table 23. Fresh water, including ice deposits, accounts for only 2.6 % (36×10^6 km^3) of the total volume. With reasonable effort, only about 10 % of the fresh water available is technically accessible to man at present (Table 24). Thus, the water supply of the earth's population will be based essentially on this volume of about 3.7×10^6 km^3.

Table 23. Assignment of water according to regions of occurrence according to [104]

Region	Volume, 10^6 km^3	Percentage
Oceans	1348	97.39
Polar icecaps, icebergs, and glaciers	27.82	2.01
Groundwater and soil moisture	8.06	0.58
Lakes and rivers	0.225	0.02
Atmosphere	0.013	0.001
Total	1384	100

Table 24. Breakdown of proportions of total fresh water usable for water supply according to [104]

Region	Percentage	Volume, 10^6 km^3
Underground (up to a depth of 800 m)	9.86	3.55
Lakes	0.35	0.13
Rivers	0.003	0.001
Atmosphere	0.04	0.014
Total	10.25	3.7

4.2. Hydrological Cycle

Many of the physicochemical properties of water, which lead to its normal appearance in nature, are due to the strong dipole character of the H_2O molecule (dipole moment: 6.13×10^{-30} Cm, 1.85 D, see also Chap. Water as a Solvent).

The fact that water occurs in nature in all three states of aggregation is of special importance. The flow of energy that reaches the earth's surface with incident solar radiation results in an average surface temperature of 15 °C [105], with considerable variation as a function of time and location. This energy input causes the evaporation of water from oceans, other surface waters, and vegetation. In the atmosphere, water vapor condenses and can be transported as visible clouds by wind. Water returns to the surface of the earth as rain, snow, and ice. It then either superficially flows away, seeps away, or contributes directly to surface water. Thus, it is again available for evaporation, partly via vegetation (Fig. 14). On an annual average, the earth's 149×10^6 km^2 of dry land receives 745 mm of precipitation (111 000 km^3), of which 477 mm (71 000 km^3) evaporates from the land and 40 000 km^3 flows into the sea [106].

Figure 14. Schematical representation of the hydrological cycle

From a global point of view, this cycle is closed (i.e., no water is lost). In individual regions, however, considerable deviations from the theoretical mean values for the mass fluxes occur due to long-range transport and climatic differences. Even in a relatively small country such as Germany, which belongs to the temperate climate zone, substantial differences are observed. Thus, the average temperature in July is between +17 °C and +18 °C in the North German lowlands, but about +20 °C in the Upper Rhine rift. The amounts of annual precipitation are between 500 and 700 mm in the North German lowlands, between 700 and 1500 mm in the low mountain ranges, and up to more than 2000 mm in the Alps [107]. The long-term average annual temperature in Germany is +9 °C. Since 1990, increases of up to 2 °C have been observed in the annual temperature and deviations of up to 5 °C in the monthly average values compared with the long-term values, have

been recorded. Despite these temperature variations with time, the precipitation balance remained almost unchanged. The long-term average value for precipitation over the area covered by the western German states (248×10^3 km^2) is 837 mm/a, while the value for the eastern states (former German Democratic Republic, 109×10^3 km^2) is 612 mm/a. Taking the small distance (a few hundred kilometers) between these two regions — that are in the same climatic zone — into consideration, this variation is remarkable. For the entire Federal Republic of Germany, this gives an average precipitation level of 768 mm/a, which corresponds to a precipitation of 274×10^9 m^3/a [105]. The water supply for Germany ensues from the difference between the long-term average values for precipitation and evaporation plus the long-term average value for inflow from other countries (Table 25) [107].

Table 25. Annual supply of water in Germany (based on 30 years of balance data, reference period 1931 – 1960)

	Precipitation levels and amounts of water	Relative values, %
Average supply of water	163.5× 1 0^9 m^3/a	100
Precipitation minus evaporation	95×10^9 m^3/a	58
Average inflow from other countries	68.5×10^9 m^3/a	42
Average precipitation	768 mm/a (274×10^9 m^3/a)	100
Average evaporation	501 mm/a (179×10^9 m^3/a)	65

4.3. Demand for Water

About 70 wt % of the human body consists of water. The WHO works from the fact that an adult weighing 60 kg must consume 2 L water per day in the form of drinking water, beverages, or food to avoid damage to his health. The quantities that apply to small children (body weight 10 kg) and infants (body weight 5 kg) are 1 and 0.75 L, respectively. A much higher water consumption per person is observed, depending on the standard of living and the economic structure. The FAO speaks of a shortage of water in a certain country or region when the annual water supply from domestic sources is <1000 m^3 per resident. Thus, a world population of 6×10^9 people will require at least 6×10^{12} m^3 water per year. Although this amount is only about 0.16 % of the total water available for drinking purposes, clearly discernible bottlenecks occur in some countries. They result from an inadequate regional supply of water. Examples of countries having a shortage of water (FAO, as of 1990) are given below, together with the amounts of water per citizen per year:

Rwanda	885 m^3
Botswana	797 m^3
Algeria	754 m^3
Burundi	663 m^3
Syria	615 m^3
Kenya	613 m^3
Tunisia	465 m^3
Israel	372 m^3
Jordan	222 m^3
Yemen	222 m^3
Mauretania	203 m^3
United Arab Emirates	188 m^3
Libya	154 m^3
Saudi Arabia	148 m^3
Egypt	35 m^3

Germany has an annual water supply of about 2000 m^3 per person. According to data released by the Statistical Federal Office (Statistisches Bundesamt), the total water requirement in 1991 was 47.9×10^9 m^3 and was distributed as shown in the following:

Cooling water, thermal power stations	28.8×10^9 m^3

Industry	11×10^9 m^3
Public water supply	6.5×10^9 m^3
Agriculture, irrigation	1.6×10^9 m^3

A breakdown of the utilization of water provided by the public water supply is given below:

Households and small businesses	68 %
Industry	13 %
Loss in the mains and consumption by waterworks	13 %
Public facilities	6 %

In households and small businesses, a daily water consumption of about 145 L per person was estimated over the past ten years. With 140 L per person (as of 1994), a downward trend has been observed in the past two years [108]. A breakdown of water consumption in households is given in the following:

Baths, showers, hygiene	40 %
Toilets	31 %
Laundry	13 %
Dish washing	7 %
Cleaning	5 %
Garden	2 %
Cooking, drinking	2 %

The length of the mains employed by the public water supply to distribute water covers about 386 000 km (estimation for 1994) [108]. The materials used for pipes (as of 1992) are listed below [109]:

Cast iron	49 %
Plastic	26.5 %
Cement	13 %
Steel	8.7 %
Other	2.8 %

In Europe, the statistical data for water consumption per person are in the range of 116 to 260 L/d (see below):

Austria	215 L
Belgium	116 L
Denmark	175 L
Finland	150 L
France	161 L
Germany	145 L
Hungary	153 L
Italy	214 L
Luxembourg	183 L
The Netherlands	173 L
Norway	167 L
Spain	131 L
Sweden	195 L
Switzerland	260 L
United Kingdom	161 L

4.4. Source of Water Used

Sources used by the public water supply in Germany as of 1994 include [108]

Groundwater	63.6 %
Springs	7.8 %

Riverbank filtration and replenishment of groundwater	15.3 %
Surface water	13.3 %

Groundwater is the most important natural source of drinking water in Germany [110].

Water resources are used regionally in different ways, depending on geographic location and on geological, pedological, and hydrological conditions (Fig. 15).

Figure 15. Regional differences in the use of water resources in Germany (as of 1994) [108]. By courtesy of the Bundesverband der deutschen Gas- und Wasserwirtschaft e. V. (Federal Association of German Gas and Water Suppliers)

As a result of their earlier history, different waters differ in their chemical composition and biological nature. Water pollution protection was the first issue of European Community environmental policy [111] and has been most extensively dealt with. The quality requirements demanded for the production of drinking water are stipulated in a European guideline [112] and, in Germany, in technical regulations [113], [114]. The requirements to be fulfilled by drinking water are also formulated in an EC guideline [115] which has to be transferred into national law of the member states. In the German decree on drinking water [116], [117], these requirements are translated into national law. The guiding principles for technical realization of the production and distribution of drinking water contained in DIN 2000 [118] have also been included partly in the decree on drinking water.

In the United States, the EPA establishes maximum contaminant level goals (MCLG) and maximum contaminant levels (MLC) as well as best available technologies for regulated water contaminants that are stipulated in the Safe Drinking Water Act (SDWA) with current amendments. A review of promulgated, proposed, and anticipated EPA drinking water regulations, which also concern disinfectants/ disinfection byproducts, analytical methods, information collection, rankings of regulatory priorities, and public notification requirements, is given in [119].

If the requirements stipulated for drinking water are not met by raw water, it must be treated before it is used as drinking water.

4.5. Water Treatment

A wide range of processes is available for the treatment of water (e.g., [120], [121]). The selection of individual treatment stages and the entire concept of treatment depend primarily on the water quality of the source used, its productivity, and consumer requirements. This means that optimum water treatment depends in each case on a particular situation, which is usually unique. For this reason, many different concepts are encountered in practice. In principle, the individual units of many treatment systems are largely similar. The water treatment concept of the Wiesbaden – Schierstein waterworks is presented in Figure 16. The large number of technical stages used permits the conversion of Rhine water to drinking water, which not only is qualitatively perfect but corresponds quantitatively to the demands of the population.

Figure 16. Principle of water treatment in the Wiesbaden – Schierstein waterworks

The versatile use of the Rhine and — despite relevant decrees and laws — the poor raw water quality found, as well as the effects of disasters and disturbances on water quality, are a real challenge to a water treatment strategy. The individual treatment stages shown in Figure 16 comply with the state of the art. In the case of better raw water conditions, some of these stages can be omitted. In the total concept of the Wiesbaden – Schierstein waterworks, the key function of the subsoil as a natural or, at least, close-to-natural treatment stage is discernible (see also [122], [123]). The bank filtrate of the river water supplements the dominant role played by groundwater in the public water supply of Central Europe. Through utilization of subsoil, nature takes on the function of technical measures in wide areas by means of its cleansing power. The reliable use of this natural self-cleansing power requires a knowledge of its capacity and responsible, future-oriented management. This includes a knowledge of the hydrological and geological situation, the allotment of protective zones with restricted use of the land, and extensive prevention of groundwater pollution [124]. The entire water utilization cycle with water above and below ground must also be regarded and assessed as a closely linked system. The German water management law (Wasserhaushaltsgesetz) [125] provides the legal framework for this purpose.

Typical concentrations of water constituents as present in some types of raw and finished water (drinking water) are given in Table 26. The limiting values found in the German decree on drinking water are given for comparison. Larger German water-supplying companies have been selected as examples. Note that the drinking water supply of the city of Munich is based on

the direct utilization of *groundwater* without technical treatment: i.e., the drinking water quality is the same as the raw water quality. The Lake Constance water supply is cited as an example of the utilization of *standing surface waters* (lakes, reservoirs), and the water supply of Düsseldorf reflects the use of the Rhine *riverbed filtrate* (riverbank filtrate) as a typical example of utilization. Accordingly, characteristic compositions are obtained for the raw waters. Groundwater has a relatively high water hardness (calcium and magnesium ions), especially when it comes from limy subsoil, has a slightly elevated nitrate content compared with the geogenic background, and otherwise shows the absence of larger influences of civilization, which is guaranteed by the protective function of the ground. These influences would be discernible from increased values for boron and phosphate. The water from Lake Constance (raw water) is correspondingly softer and exhibits the characteristic chemical features of surface water, e.g., a noticeable concentration of organic water constituents (DOC). In addition, slight anthropogenic influences are discernible, which can be seen from the fact that phosphate and the widely used EDTA are detected. The raw water quality of the Rhine bed filtrate is characteristic of the load of a variedly and greatly used flowing body of water, a load that is reduced by the natural cleansing power of the ground.

Table 26. Typical concentrations of constituents and properties of raw and drinking water compared to selected limiting values in the decree on drinking water

For the two treated waters, comparison of raw water and drinking water data shows clearly that many parameters are not significantly changed after treatment. The effects of oxidative and adsorptive water treatment steps are observable in the improvement of both the organoleptic values, such as color, turbidity, and odor, and the microbiological parameters (decrease in coliform organisms and number of colonies). These quality criteria also represent the primary target values of drinking water treatment. Furthermore, a decrease is observed in the values of those parameters that are partially (spectral absorption coefficient, oxidizability) or exclusively (DOC) a measure of the concentration of organic water constituents [126]. The elimination of organic water constituents is important to reduce the danger of future regrowth of bacteria in the mains during water distribution and also to restrict the formation of trihalomethanes during future chlorination. Halogen-containing disinfection byproducts can also increase the AOX value produced by industrial wastewater. The increase of phosphorus in the finished water from the riverbank filtrate is due to the addition of a phosphate – silicate mixture as a corrosion inhibitor.

Despite the quality improvement of surface water (e.g., [127] discernible since the 1980s, the need for efficient water treatment continues to exist. This results from the obligation of the public water supply system to provide sufficient amounts of qualitatively perfect drinking water at all times. In addition, precautions against accidents and disasters that can impair the quality of surface waters and are not excludable require appropriate protective measures.

Water for *technical use* is also of particular significance. Great demands are made on boiler feed water, process water, water for pharmaceutical and food technology uses, and water for swimming pools. These demands can be met only by purpose-oriented water treatment processes (see e.g., [128], [129] and Chaps. Ion Exchange and Membrane Separation Processes in Water Treatment). As a rule, a combination of various process steps is required.

[Top of Page]

5. Adsorption Processes in Water Treatment

Klaus Johannsen and R. Scott Summers

5.1. Introduction

Adsorption processes are used for the removal of dissolved organic substances for production of drinking water from both surface and groundwaters. The most important adsorbent for water treatment is activated carbon, and it was initially applied to improve the taste and odor of water. Activated carbon is also used to remove micropollutants, such as pesticides and halogenated hydrocarbons, and to limit the formation of disinfection byproducts (DBPs), such as trihalomethanes, by removal of natural organic matter (NOM), which can form disinfection byproducts upon chlorination. Activated carbon is applied in two forms: powdered activated carbon (PAC) and granular activated carbon (GAC). Powdered activated carbon is added as a suspension to the water to be purified and removed by sedimentation or filtration. In GAC treatment, fixed beds are used that contain the activated carbon. Monographs give an overview of the fundamentals and application of activated carbon in drinking water treatment [130-134].

5.2. Properties of Activated Carbon (see also ⟶ Carbon, ⟶ Carbon – Mechanical Properties, ⟶ Carbon – Adsorption Properties)

The most common raw materials used in the production of activated carbons are bituminous coal, peat, wood, lignite, coke, and coconut shells. Typical production processes include charring by pyrolytic carbonization of the raw material at <700 °C, followed by thermal activation with oxidizing gases such as steam, CO_2, and air at 800 – 1000 °C. Development of the pore structure in this manner yields internal surface areas of 500 – 1100 m^2/g. The ability of activated carbon to adsorb large quantities of material is related directly to its porous nature. Pore volume and surface area distributions are determined by mercury porosimetry and nitrogen and benzene absorption. The intitial portions of the nitrogen adsorption isotherms are often utilized to calculate the total pore surface area of an adsorbent. Standardized aqueous test methods, such as the molasses test, methylene blue number, phenol test, and iodine number, have been developed to evaluate the equilibrium adsorption capacity of PAC or GAC. In particular, the iodine number gives a good indication of the microporosity and is often correlated with the BET surface area [130], [131].

To minimize operational problems when using GAC in packed beds, the particle size and particle-size distribution must vary only within certain limits. Typical average particle diameters of *granular activated carbon* are in the 0.9 – 1.6-mm range. Smaller particles yield faster overall adsorption kinetics; however, too many particles smaller than 0.5 mm may cause high pressure losses in the fixed bed. Typical average particle diameters of *powdered activated carbon* are between 0.01 and 0.04 mm. Smaller particle sizes impede handling and separation of PAC. Values for the material density of GAC are in the 1800 – 2000 kg/m^3 range. The dry particle density of GAC (i.e., dry mass per particle volume) is between 500 and 850 kg/m^3, while its wet particle density is between 1300 and 1500 kg/m^3. The apparent (bed, bulk, or filter) density (i.e., dry mass per vessel volume) of GAC is in the 300 – 500-kg/m^3 range; that for PAC is slightly higher (400 – 700 kg/m^3) [130], [131], [133], [134].

5.3. Adsorption Theory (⟶ Adsorption)

Adsorption is the accumulation of a substance, the adsorbate, onto a solid, the adsorbent; it is driven by physical or chemical forces.

Physical adsorption is based on nonspecific electrostatic forces, such as dipole – dipole interactions, hydrogen bonding, and van der Waals forces. In general, nonpolar compounds dissolved in a polar solvent (water) are more strongly adsorbed by a nonpolar adsorbent (activated carbon). Compared with chemical adsorption (chemisorption), physical adsorption is less specific, operates over longer distances, has weaker forces and energies of bonding, and is reversible to a greater degree.

Chemisorption forces approach that of a covalent or electrostatic chemical bond, and because of the specificity of the bond

between adsorbate and surface, the adsorbate cannot accumulate at more than one molecular layer; i.e., a monolayer of adsorbate is formed. In water treatment, physical adsorption dominates.

In general, adsorbability on activated carbon is inversely related to the water solubility of the adsorbate and the pH. The adsorption of a substance increases with increasing number of double bonds (π-bonds) in the molecule, increasing molecular size, and increasing ionic strength of the solution. However, for high molar mass compounds such as humic substances, size exclusion can be observed [131]. A good relationship between the surface area or volume of micropores of activated carbons and their adsorption capacity for several compounds has been found [131], [134].

5.4. Adsorption Equilibrium (⟶ Adsorption – Thermodynamics, Equilibria, and Heat of Adsorption)

Adsorption equilibrium studies — termed isotherms, because they are conducted at constant temperature — establish the relationship between the concentration of adsorbate in the liquid phase *c* and its concentration in the solid phase *q*. For determination of equilibria, the *bottle point technique* [131], [134] is normally used. Here, defined quantities *m* of PAC or ground GAC are added to a series of bottles containing a volume of solution *L* with an initial adsorbate concentration c_0. The samples are mixed until equilibrium is reached: i.e., no measurable change in the liquid-phase concentration occurs. Activated carbon is separated from the liquid phase, and *c* is determined. Based on a mass balance for fresh carbon, the solid-phase concentration *q* is calculated according to

$$q = L(c_0 - c)/m \tag{5.1}$$

The equilibration time depends on particle size. For carbon with particle sizes <0.1 mm, an equilibration time of 2 – 5 d is adequate.

The two most commonly used models to describe the equilibrium relationship between *c* and *q* are the Langmuir [135] and the Freundlich equations [136]. Both are two-parameter equations. The Langmuir equation has a maximum solid-phase concentration value. In the low-concentration range, a linear relationship exists between the concentration of adsorbate in the solid and the liquid phase. The Freundlich equation is a empirical power function of

$$q = K_F c^n \tag{5.2}$$

where K_F is the Freundlich constant and *n* is the Freundlich exponent. These two parameters can be determined from the measured data by nonlinear regression of *c* and *q* or by linear regression of log *c* and log *q*. The slope of log *c* versus log *q* is equal to the exponent *n*, and the value of *q* at *c* = 1 equals K_F. The Freundlich equation is most often used to describe experimental data, but it is valid only in the concentration range of these data. Experimental adsorption data for a variety of compounds and carbons are summarized in [131], [137], [138].

When more than one adsorbable component is present in a solution, the compounds compete with each other for available adsorption sites on the carbon surface. If the complete reversibility of adsorption is assumed, the ideal absorbed solution (IAS) theory accounts for these interactions by using data only from the single-solute isotherms [139-143]. The ideal absorbed solution theory has the flexibility to incorporate many of the single-solute isotherm model equations; thus, for multicomponent systems it can be used with the model that best describes the single-solute data. The use of the IAS theory coupled with the Freundlich equation was applied successfully to multicomponent systems with solutes of similar characteristics [131]. However, in other situations, the IAS theory was not as successful and modifications were made to account for unequal competition for active sites and irreversible adsorption [144]; changes in the Freundlich parameters at low concentration [141], [145]; and differences in accessible surface area [146].

Most (80 – 95 %) of the natural organic matter in water is adsorbable. However, the composition of natural organic matter in water is complex; only a small percentage of the components can be identified specifically, and quantification of the few identifiable compounds is problematic because of their low concentration. Typically, NOM is quantified by the amount of dissolved organic carbon or the UV absorbance at 254 nm. This complexity of natural organic matter presents a problem in describing adsorption equilibria. The *adsorption analysis approach*, developed to describe the adsorption of an unknown mixture, divides NOM into fictive components of different adsorbabilities and uses the IAS theory to quantitate their competition [131]. The adsorption analysis approach has been applied successfully to several waters to demonstrate the influence of initial NOM concentration, pH, treatment processes, carbon type, and presence of tracer compounds. One drawback is that it does not account for the effects of size exclusion, which is likely important for the molecular size range of NOM [131].

In most polluted raw water, the NOM concentration is much higher than that of specific micropollutants to be removed. The adsorption capacity of carbon for the specific micropollutants can be lowered significantly in the presence of adsorbing NOM. Figure 17 illustrates the influence of background NOM on the adsorption isotherms of the pesticide metazachlor [*N*-(2,6-dimethylphenyl)-*N*-(1-pyrazolylmethyl)-chloroacetamide] [147]. At both pesticide initial concentrations c_0, the presence of 10 mg/L DOC causes a reduction of ca. 60 % in the adsorption capacity. Furthermore, Figure 17 shows the impact of the initial concentration of pesticide on the isotherm. At c_0 = 2 µg/L, the adsorption capacity is much lower than at c_0 = 200 µ/L for both DOC values. Thus, even the presence of 0.3 mg/L DOC causes a capacity reduction at the low initial concentration of the micropollutant.

Figure 17. Influence of initial concentration and background DOC concentration on metazachlor adsorption isotherms [147]

These effects can be explained by the occurrence of competitive adsorption between metazachlor and background NOM. Models have been developed that calculate the competitive adsorption between target compound and background NOM using the IAS theory [147-150]. These competitive effects have been found for most pesticides, but not for some chlorinated hydrocarbons [131].

5.5. Adsorption Kinetics (⟶ Adsorption – Kinetics)

Although adsorption at an active site of the carbon surface is a fast reaction, the resistance to mass transfer of the adsorbate from the bulk liquid to the adsorption sites is high enough that the overall kinetics of the adsorption process must be considered in the design of both PAC and GAC systems. The driving force for mass transfer is the concentration difference of the adsorbate in the bulk solution and in the carbon particle. This exists as long as the solid-phase concentration on carbon is not in equilibrium with the liquid-phase concentration.

For the fixed-bed application of GAC, the breakthrough curve for the ideal plug-flow reactor (PFR) with no mass-transfer resistance is shown in Figure 18 (curve a). This ideal breakthrough curve may be used to define the time at which the amount of adsorbate applied to the GAC bed equals the amount that can be adsorbed at equilibrium. This time is sometimes referred to as the stoichiometric breakthrough time t_{stoich} and can be calculated from the following mass balance equation and isotherm data:

$$c_0 t_{stoich} \dot{V} = q_0 m \tag{5.3}$$

where c_0 is the influent concentration, q_0 is the solid-phase concentration in equilibrium with c_0, $\dot{V}$ is the volumetric flow rate, and m is the adsorbent mass. Mass-transfer resistances, axial dispersion, and unfavorable equilibrium conditions can cause the breakthrough curve to deviate from ideal PFR behavior as shown for a single solute in Figure 18 (curve b). The total amount of solute adsorbed should be the same for the ideal PFR and the case with mass-transfer resistance and is the difference between the quantity applied and that in the effluent. This can be calculated by the following mass balance:

$$\dot{V} = \int_0^\infty (c_0 - c_e(t))\mathrm{d}t = q_0 m \tag{5.4}$$

where c_e is the effluent concentration. The value of the integral corresponds to the area bounded by the $c = c_0$ line and the breakthrough curve. It represents the total capacity of the GAC in the reactor. Since the total amount adsorbed satisfies Equation (5.4) regardless of the shape of the breakthrough curve, the shaded areas F_1 and F_2 in Figure 18 must be equal. If they are not equal, the calculated capacity from the isotherm q_0 does not agree with the column capacity.

Figure 18. Comparison of breakthrough curves

a) Ideal (negligible mass-transfer resistance); b) Single solute; c) Specific solute in a mixture; d) NOM

In practice, solutes to be removed from water are present in mixtures and, as discussed in Section Adsorption Equilibrium , the presence of other adsorbates — both more weakly and more strongly adsorbing — will decrease adsorption of the target compound. This is also illustrated in Figure 18 (curve c). The concentration and adsorbability of the different components of the mixture determine the shape and time of the breakthrough curve of the target compound. If the mixture contains high concentrations of solutes that are adsorbed more strongly, c_e of the target compound may become greater than c_0 (i.e., “overshoot” may occur). If the mixture contains mostly specific compounds, breakthrough of the target compound can be calculated by using competitive adsorption models. If significant concentrations of NOM are present, competitive adsorption models are not viable, when a component of NOM is adsorbed irreversibilly. Compared to the target compound, this NOM component progresses deeper into the GAC bed and is adsorbed first. Because of its irreversible adsorption, this NOM component “blocks” the GAC surface (fouling), thus reducing the adsorption capacity for the target compound. Currently, only site-specific calibrated models can simulate this adsorption behavior [131], [134].

The breakthrough behavior of NOM is important in controlling the formation of DBPs and is illustrated in Figure 18 (curve d). Typically, an immediate breakthrough of 5 – 20 % is displayed, and if this level is maintained for any length of time, this fraction is considered nonadsorbable as shown in Figure 18. If c_e begins to rise immediately, then the immediate breakthrough may also include a fraction due to external mass-transfer resistance. The NOM breakthrough curve normally begins to plateau at a value 10 – 30 % lower than c_0, which can be attributed to very slow adsorption or biological degradation [131], [134].

A wide range of mathematical models have been developed to account for equilibria and kinetic components such as axial dispersion, external (film) mass transfer, and intra particle pore and surface diffusion [131]. The most commonly used model for micropollutants is the plug-flow homogeneous surface diffusion model, which includes external mass transfer and intra particle surface diffusion, and can utilize the IAS theory and the Freundlich equilibria model [131]. A simplified model considers the internal mass transfer as a linear driving force [151], [152]. For NOM adsorption the pore diffusion component seems to be important.

5.6. Biological Processes

Most drinking water sources contain a biodegradable NOM component in a concentration of 5 – 20 %, which is increased an additional 5 – 20 % by ozonation. Since this fraction is not removed in most treatment plants, biological degradation occurs to

some degree in all GAC contactors. In addition to removing some of the biodegradable NOM fraction and associated DBP precursors, biological degradation activity on GAC can extend its adsorption capacity by reducing the overall organic load to the GAC. The negative aspects of biological activity on GAC include growth of zooplankton in the GAC bed, increased microorganism concentrations in the effluent, release of colonized GAC fines that are difficult to disinfect, and under anaerobic conditions, the formation of taste- and odor-causing compounds. Depending on temperature and biodegradability, component bioacclimation times are in the range of 5 – 30 d. Those GAC columns that are run for extended periods of time and reach a steady-state removal level, as shown in Figure 18 for NOM, are often termed biologically activated carbon (BAC) systems. Biological activated carbon systems rely on biodegradation for removal of pollutants, but the GAC adsorption capacity attenuates influent pulses, which allows the biomass to degrade desorbing substances. Compared to other support media such as sand, GAC also has the advantage of providing larger accessible surface area for attachment of biomass. When preozonation of water is used, the interaction with GAC must be considered, because ozonation increases biodegradability but decreases the adsorbability of NOM on GAC by formation of polar substances such as aldehydes, ketones, and ketoacids. An ozone dose in the range of 1.0 – 0.5 g O_3 per gram DOC is sufficient for disinfection and NOM oxidation without significantly decreasing adsorbability [131], [134].

5.7. Design of GAC Systems

The important parameters and typical values used to characterize the design and operation of GAC adsorbers are listed below [131], [134]:

Bed volume V_F	10 – 50 m^3
Cross-sectional area A_F	5 – 30 m^2
Length l	1.8 – 4 m
Filter velocity v_F	5 – 15 m/h
Empty bed contact time *EBCT*	5 – 30 min
Operation time t_F	100 – 600 d
Throughput *BV*	4000 – 30 000 m^3/m^3
Carbon use rate *CUR*	5 – 50 g/m^3

Of particular importance are the filter velocity v_F (also termed the superficial linear velocity or surface loading rate), which is defined as

$$v_F = \frac{\dot{V}}{A_F} \tag{5.5}$$

and the empty-bed contact time *EBCT*, which is defined as

$$EBCT = \frac{V_F}{\dot{V}} = \frac{l}{v_F} \tag{5.6}$$

For a given flow rate, v_F determines the filter area, while *EBCT* determines the length and volume of the carbon bed, both of which influence the capital costs of a GAC system. The *EBCT* also has an impact on operation and maintenance costs, because shorter *EBCT*s lead to faster breakthrough of pollutants and subsequently more frequent replacement of the GAC bed is required. The throughput parameter in bed volume *BV* is a normalized expression of the volume of water treated V_L or the filter operation time t_F and is defined as

$$BV = \frac{V_L}{V_F} = \frac{t_F}{EBCT} \tag{5.7}$$

The carbon use rate *CUR* is the mass of GAC required to treat a volume of water to achieve a given treatment objective and is defined by

$$CUR = \frac{m}{V_L} = \frac{\varrho_F}{BV} \tag{5.8}$$

where ϱ_F is the density of the filter layer. For a given flow rate, *CUR* dictates the GAC demand from which the cost of GAC replacement or reactivation can be calculated. Background NOM decreases the GAC adsorption capacity for specific organic compounds and thus increases *CUR*. Values of *CUR* predicted from distilled water isotherm data were compared with the observed *CUR* of pilot and full-scale column runs for which breakthrough data were available [153]. Figure 19 shows the relationship between the natural water correction factor (observed *CUR*: distilled water *CUR*) and the distilled water *CUR*. For compounds that are strongly absorbed by the carbon bed (i.e., low *CUR*), the natural water correction factors are higher (10 – 100) than for substances that are adsorbed only weakly. This is due to the fact that in treating strongly adsorbed compounds, the GAC is exposed to NOM for a longer time, thus, more fouling occurs.

Figure 19. Relationship between natural water correction factor and distilled water carbon usage rate [153]

In groundwater treatment plants, the GAC is normally placed at the end of the treatment train but before final disinfection. In surface water treatment plants, GAC can be used as a filter adsorber or placed as a stand-alone unit after filtration, termed the postfilter adsorber. In both cases, predisinfection of water with chlorine-based disinfectants should be avoided because the disinfectants can react with the GAC and thus reduce its adsorption capacity for organic compounds and form undesired chlorinated compounds [134]. Old water filters that have been retrofitted as filter adsorbers tend to have low *EBCT*s, 3 – 9 min, which limits their application in most cases to taste and odor improvement and chemical spill control. Postfilter adsorbers generally have longer *EBCT*s, 10 – 30 min. They can be used effectively to control a wider range of compounds, including micropollutants, NOM, and DBP precursors.

Prediction and Simulation of GAC Breakthrough Behavior. For site-specific design purposes, a variety of approaches have been applied to predict or simulate GAC breakthrough behavior. Parallel pilot columns that utilize the same GAC and influent water as the full-scale system are accurate and reliable predictors of breakthrough behavior [154], [155]. They also have the advantage of not requiring the use of numerical models in interpretation of the data, but they have the same operation time as the full-scale system. Another approach is to collect isotherm and adsorption kinetic data and use the data as input to fixed-bed numerical models for predicting breakthrough [131], [151], [152], [156], [157]. Some extensions of these models have been made to take into account the impact of NOM on the breakthrough behavior of micropollutants [131], [147].

Minicolumns utilize small particle and column sizes to decrease the operating time of a column to a small percentage of that required in the full-scale column. *Small-scale columns* are minicolumns in which similitude to full-scale GAC systems has been maintained. The relationship among particle size, column length or *EBCT*, and operation time of small-scale and full-scale columns is determined by dimensional analysis. Successful application of small-scale columns yields breakthrough curves that are equivalent to those of a full-scale adsorber. The method was pioneered by FRICK [131] and was developed further and applied extensively by CRITTENDEN and coworkers [158-160], leading to the rapid small-scale column test (RSSCT). The major problem is that the impact of background NOM on the adsorption capacity and diffusion kinetics of micropollutants is not always reflected accurately in small-scale columns. Rapid small-scale column tests have been used successfully to predict the breakthrough of NOM and DBP precursors [160], [161].

5.8. Design of PAC Systems

Powdered activated carbon can be applied effectively to control periodic taste and odor problems and spills of synthetic organic compounds in raw source water. The PAC dosage (i.e., the mass of PAC per volume of water treated) typically ranges from 5 to 50 mg/m^3 for the improvement of taste and odor. Long-term removal of specific compounds, such as pesticides and volatile organic carbons, NOM, and DBP precursors is possible but usually only at uneconomically high activated carbon dosages. If long-term high dosages of PAC are required, GAC systems are usually more economical. The advantages of PAC compared to GAC are (1) low capital costs, because PAC is added to existing contactors; (2) rapid utilization of the adsorption capacity, because PAC is 25 times smaller than GAC; and (3) flexibility in operation, because the dosage, and to some degree the point of application of PAC, can be controlled easily. Its disadvantages are that PAC cannot be reactivated and that it can be carried over into the distribution system [131], [134].

Powdered activated carbon can be applied dry or as a slurry at several points in a surface water treatment plant, as shown in Figure 20 (points A – E). The most common points of addition are at the coagulant rapid mixing tank (B) and the flocculation tank (C). The PAC is removed from the process stream during sedimentation and filtration, and effective contact times of 30 – 60 min can be achieved. Addition of PAC at the raw water intake (A) results in longer contact times, especially if presedimentation is employed. Each PAC addition point has advantages and disadvantages with respect to contact time, kinetics, and competing organic compounds. The PAC added at point A is not incorporated initially within the floc particles, as it is when added at points B and C; i.e., addition at point A allows for faster adsorption kinetics. When PAC is added at point A, the disadvantage is increased competition for active sites from organic compounds that are lated removed by coagulation. The PAC added at point D will have the shortest contact time, but incorporation of floc and competing organic compounds is decreased. When PAC is added at point E, incorporation of competing organic compounds and floc is at a minimum and the PAC is retained within the filter for longer times. This all results in an increased adsorption capacity, thus improving effectiveness. However, filter run times are shortened, and PAC breakthrough into the distribution system must be avoided because the presence of PAC in the distribution system can lead to bacterial regrowth problems. The retention of PAC particles within filters can be aided with the addition of polyelectrolytes [131], [134].

Figure 20. Flow sheet for PAC application in a conventional surface water treatment plant

5.9. Reactivation of GAC

Activated carbon has a finite adsorption capacity, and after exhaustion of this capacity, the used GAC must be replaced with fresh or reactivated GAC. Reactivation conditions are similar to those employed in manufacturing activated carbon by thermal activation, which means that part of the carbon surface may be included in the reaction. Typically, thermal reactivation of GAC occurs in four stages: (1) thermal desorption of the absorbed compounds; (2) thermal decomposition of the adsorbed compounds followed by desorption of the decomposition products; (3) carbonization of the nondesorbed products formed during thermal decomposition or chemisorbed during the adsorption step; and (4) surface reactions between the carbonaceous residuals and water vapor or oxidizing gases to form gaseous products. Each of these stages is associated with a particular temperature range and consists of several simultaneous steps. If properly designed and operated, reactivation can yield 100 % recovery of the adsorption capacity. However a 5 – 15 % loss of GAC occurs during a reactivation cycle, which includes backwashing, transportation, and reactivation; this necessitates the use of fresh makup GAC [131], [134].

6. Ion Exchange

Wolfgang Höll

(see also ⟶ Ion Exchangers)

In water technology, ion-exchange resins are used to eliminate cations or anions and replace them with other cations or anions. In this way the composition of the components of the water is changed, and as a consequence, a change in water properties occurs. Among the components of natural water carbonic acid and its dissociation products play a particular role because these species form the dominant buffer system of water. This buffer system is affected by almost every ion-exchange process. Beyond the mere exchange of ionic species the properties of water are therefore influenced in a way that is characteristic for each type of exchange. The fundamentals of ion exchange and aspects of its application have been presented in several books and innumerable publications [162-167]. This chapter illustrates the influence of ion exchange on the properties of the water treated, i.e., its chemical state, which may be characterized by pH value and alkalinity.

6.1. Fundamentals

6.1.1. *Characterization of the Chemical State of Water*

Inorganic Components of Natural Water. The main inorganic components of natural water include the following:

Cations of strong electrolytes	Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}
Anions of strong electrolytes	SO_4^{2-}, NO_3^-, Cl^-
Species of carbonic acid	CO_2, H_2CO_3, HCO_3^-, CO_3^{2-}
Water and its dissociation products	H_2O, H^+, OH^-
Silica	SiO_2

In addition, natural water usually contains nonionic impurities (dispersed substances that cause turbidity, colorants, colloids, or organic matter), which are not discussed in this chapter.

Dissociation of Carbonic Acid and Water and the Solubility of Calcium Carbonate. The above list shows that carbonic acid is present in water in the form of four different species. If nondissociated H_2CO_3 is ignored because of its low concentration, the sum of the concentrations of carbonic acid species — usually designated the total inorganic carbon (TIC) — is

$$\mathrm{TIC} = c(\mathrm{CO_2}) + c(\mathrm{HCO_3^-}) + c(\mathrm{CO_3^{2-}}) \tag{6.1}$$

The concentrations of CO_2, HCO_3^-, and CO_3^{2-} are linked by the dissociation of carbonic acid [dissociation constants K_1 (T, I) and K_2 (T, I), where I denotes ionic strength and T is temperature].

The ionic strength I is defined by

$$I = 0.5 \sum z(i)\, 2c(i)$$

where z (i) is the valence of species i. Further dependencies are normally negligible. By using the ionic strength, activity coefficients of monovalent species can be calculated according to

$$\log f(i) = -\frac{0.5\sqrt{I}}{1 + 1.5\sqrt{I}} + CI$$

For I < 0.1 mol/L the second term is negligible. Activity coefficients of bivalent species result from f (z = 2) = f (z = 1)^2.

The dissociation constants K_1 and K_2 (for Θ = 25 °C, I = 0 mol/L) can be calculated according to [168], [169]

$$pK_1^0 = \frac{17052}{T} + 215.21 \cdot \log T - 0.12675\,T - 545.560$$
$$pK_2^0 = \frac{2902.39}{T} + 0.02379\,T - 6.4980$$

The relative amount of negative charges of carbonic acid species is expressed by the so-called equivalent factor Φ:

$$\phi = \frac{c(HCO_3^-) + 2c(CO_3^{2-})}{TIC} \tag{6.2}$$

which lies in the range $0 \leq \Phi \leq 2$ [170].

The dissociation of water molecules is characterized by the ionic product of water:

$$c(H^+) \cdot c(OH^-) = K_W(T, I) \tag{6.3}$$

If the liquid phase is in equilibrium with solid $CaCO_3$, the concentrations of the respective ions are linked by the solubility product:

$$c(Ca^{2+}) \cdot c(CO_3^{2-}) = K_L(T, I) \tag{6.4}$$

The solubility product K_L^0 of $CaCO_3$ (for Θ = 25 °C, I = 0 mol/L) can be calculated from [171]

$$\log K_L^0 = -8.468 - 507.59\left(\frac{1}{T_0} - \frac{1}{T}\right) - 18.65\left(\ln\frac{T_0}{T} + \frac{T}{T_0} - 1\right)$$

with T_0 being 298.15 K.

m and p Alkalinities. One of the fundamental properties of each electrolyte solution is its electroneutrality. Given the species on the above list, this condition can be expressed as

$$\begin{aligned} &2c(Ca^{2+}) + 2c(Mg^{2+}) + \\ &c(Na^+) + c(K^+) + c(H^+) \\ &= 2c(SO_4^{2-}) + c(NO_3^-) + c(Cl^-) \\ &+ c(HCO_3^-) + 2c(CO_3^{2-}) + c(OH^-) \end{aligned} \tag{6.5}$$

Rearrangement of this equation with respect to the origin of the species from either strong or weak electrolyes yields

$$\begin{aligned} &2c(Ca^{2+}) + 2c(Mg^{2+}) + c(Na^+) + c(K^+) \\ &-2c(SO_4^{2-}) - c(NO_3^-) - c(Cl^-) \\ &= c(HCO_3^-) + 2c(CO_3^{2-}) + \\ &c(OH^-) - c(H^+) \end{aligned} \tag{6.6}$$

The algebraic sum of equivalents on the right-hand side of this equation can be determined approximately by titration with methyl orange (color change at pH 3.1 – 4.4) as indicator. Both sides of Equation (6.6), therefore, define the so-called methyl orange alkalinity (*m* alkalinity, total alkalinity, TAC) [170]. By means of the abbreviation

$$\Delta = c(OH^-) - c(H^+) \tag{6.7}$$

the right-hand side of Equation (6.6>) can be written as

$$m = TIC \cdot \phi + \Delta \tag{6.8}$$

Carbonic acid-bearing solutions are usually characterized also by a second quantity which is derived from titration with phenolphthalein as the indicator (color change at pH 8.2–9.8), the so-called phenolphthalein alkalinity (*p* alkalinity):

$$\begin{aligned} &p = -c(CO_2) + c(CO_3^{2-}) + \\ &c(OH^-) - c(H^+) \end{aligned} \tag{6.9}$$

This relationship results from the definition of *m* alkalinity and from the condition

$$TIC = m - p \tag{6.10}$$

For natural water with pH values between 6 and 8.5 the *m* alkalinity approximately equals the concentration of HCO_3^- ions and the value of the *p* alkalinity that of carbon dioxide. The advantage of using *m* and *p* alkalinities is that they allow characterization of the water without tedious analyses of all inorganic components [170].

Interdependence Between Carbonate Balance and Solubility of Calcium Carbonate. In natural water the solubility of calcium carbonate is almost never adjusted correctly. The water is either oversaturated or undersaturated with $CaCO_3$. The state of saturation can be characterized by the saturation index *S I*:

$$SI = \log \frac{c(Ca^{2+}) \cdot c(CO_3^{2-})}{K_L} \tag{6.11}$$

For positive values of SI, $CaCO_3$ can be precipitated from water; for negative values, it can be dissolved.

The content of the components unaffected by either the precipitation or the dissolution of $CaCO_3$ is characterized by the parameter $m - 2\,c\,(Ca^{2+})$, which remains constant in both cases. Subtracting $2\,c\,(Ca^{2+})$ from both sides of Equation (6.8) and expressing $c\,(Ca^{2+})$ on the right-hand side by Equation (6.11) finally yield the relationship

$$\begin{aligned} &TIC^2 \cdot \phi + TIC \cdot \{\Delta - [m - 2c(Ca^{2+})]\} \\ &-2 \cdot K_L \left[1 + \frac{c(H^+)}{K_1} + \frac{c(H^+)^2}{K_1 K_2}\right] \cdot 10^{SI} \end{aligned} \tag{6.12}$$

which gives the interdependence between the carbonate balance and the solubility of calcium carbonate for an arbitrary value of the parameter $m - 2\,c\,(Ca^{2+})$ [170], [172].

6.1.2. *Representation of the Chemical State of Water*

One of the classical graphic representations of the carbonate balance and thus of the chemical state of water was introduced by TILLMANNS, who plotted the concentration of "free" carbonic acid [$c\,(CO_2)$] as a function of $c(HCO_3^-) + 2\,c(CO_3^{2-})$ [173]. With respect to this familiar plot, a generalized modification giving the (negative) p alkalinity as a function of the m alkalinity was chosen to illustrate the changes of the state of water in ion-exchange processes. The generalization is obtained by combining Equations (6.8) and (6.10) to yield the following relationship:

$$p = m \cdot \frac{\phi - 1}{\phi} + \frac{\Delta}{\phi} \tag{6.13}$$

Since both Φ and Δ are functions of pH, Equation (6.13) represents the equation of a straight line at constant pH [170]. The set of lines is plotted in Figure 21. The state of equilibrium with solid $CaCO_3$ corresponding to Equation (6.12) is given by the set of curves for which $m - 2\,c\,(Ca^{2+})$ has a given constant value. Since TIC cannot be negative, all possible states of solutions of salts of carbonic acid must lie above the line with $p = m$. The plot allows a simple representation of most of the changes of the chemical state of water.

Figure 21. Interdependence of m alkalinity, p alkalinity, and pH (temperature 25 °C, ionic strength I = 0 mol/L)

Any mathematical calculation of carbonate balance requires that four quantities be known (i.e., temperature, ionic strength, and m and p alkalinities). By this means, an arbitrary fifth quantity can be calculated. Graphical plots allow representation of the interdependence of only three quantities; two more must be assumed to be constant. To fulfill this condition, all calculations were made for 25 °C and a constant ionic strength of 0 mol/L. The latter assumption is a crude simplification in view of the changes in composition of water. However, ionic strength affects only the calculated pH values (through the activity coefficients), whereas the m and p alkalinities remain unaffected.

Further graphical representations of the chemical state have been developed by HALLOPEAU and by CALDWELL and LAWRENCE [174], [175]. However, these plots are not discussed here.

6.1.3. *Ion Exchangers*

(⟶ Ion Exchangers, ⟶ Ion Exchangers – Properties) [165]

Resin Structure and Type. An ion-exchange resin consists of a polymer matrix containing functional groups. The matrix consists of polystyrene or of acrylic polymers, both cross-linked by means of divinylbenzene (DVB). The DVB concentration normally varies between 4 and 12 %. However, for particular purposes, resins with either less than 4 % or up to 25 % DVB are available.

The ability to exchange ionic species is due to the functional groups present in the resin. Either these must be fixed within the matrix structure by a suitable functionalization step during synthesis or they are already part of the organic monomers. According to the types of functional groups and their degree of either dissociation or protonation, strongly and weakly acidic or basic ion-exchange resins can be distinguished. Functional groups of common exchange resins are summarized below:

Strongly acidic $-SO_3^-H^+$
Weakly acidic $-COOH$
Strongly basic

	$-N^+(CH_3)_3OH^-$ (Type I)
	$-N^+(CH_3)_2C_2H_4OH^-$(Type II)
Weakly basic	$-NR'_2 \cdot H_2O$
	$-NRH' \cdot H_2O$
	$-NH_2H_2O$

Dissociation of Functional Groups. The dissociation of functional groups of cation and anion exchangers can be written as

$$\underset{\text{(cation-exchange resin)}}{\overline{R-H} \rightleftharpoons \overline{R^-} + \overline{H^+}} \tag{6.14a}$$

$$\underset{\text{(anion-exchange resin)}}{\overline{R-H^+} \rightleftharpoons \overline{R^-} + \overline{H^+}} \tag{6.14b}$$

Overbars refer to the resin phase. By applying the law of mass action, the following constants are obtained:

$$K_c = \frac{\overline{R^-} \cdot \overline{H^+}}{\overline{R-H}} \tag{6.15a}$$

$$K_a = \frac{\overline{R} \cdot \overline{H^+}}{\overline{R-H^+}} \tag{6.15b}$$

where the indices c and a denote cationic and anionic resins.

The p*K* values can be derived from these constants:

$$pK = -\log K \tag{6.16}$$

The p*K* values of cation- and anion-exchange resins are summarized in the following:

Strongly acidic	<1
Weakly acidic	4 – 6
Strongly basic	>13
Weakly basic	6 – 9

The range of operation of different resin types can be derived by means of p*K* values. If pH $\simeq$ p$\bar{H}$, the percentage of dissociation of charge-bearing functional groups exceeds 50 % in cation exchangers for pH > p*K* and in anion exchangers for pH < p*K*. As a crude rule, the p*K* therefore represents the limit of applicability of an exchange resin.

6.2. Cation-Exchange Processes

6.2.1. *Strongly Acidic Resins in the Na^+ Form*

Application of strongly acidic resins in the sodium ion form is the classical ion-exchange process for water softening. Softening makes possible the elimination of alkaline-earth ions from water. These species may cause troublesome $CaCO_3$, $Mg(OH)_2$, and $CaSO_4$ scales on heat-transfer surfaces. Furthermore, increased concentrations of alkaline-earth ions require increased consumption of detergents in washings. Softening processes have been introduced in industrial and drinking water treatment, both in municipal water treatment systems and in home softeners [176-178]. An equilibrium diagram for water softening is shown in Figure 22.

Figure 22. Equilibrium diagram for water softening. The following raw water composition is assumed: *c* (Ca^{2+}) = 3 mmol/L, *c* (Mg^{2+}) = 0.5 mmol/L, *c* (Na^+) = 1 mmol/L, *c* (Cl^-) = 2 mmol/L, TIC = 5.5 mmol/L

R = Raw water; P = Product water

In terms of a formal chemical reaction, the process reads as follows:

$$\overline{R-SO_3^-Na^+} + (Ca^{2+}, Mg^{2+}) \rightleftharpoons \overline{R-SO_3^-(Ca^{2+}, Mg^{2+})} + Na^+ \tag{6.17}$$

Symbols in parentheses indicate the stoichiometry of the exchange. Because of the greater affinity of the resin for bivalent species, calcium and magnesium ions are removed very efficiently. Sodium chloride solutions (brine) are used to regenerate exhausted resin. In practice, the resin is converted only partly to the sodium form; the relative amount of loading is about

50 % of the exchange capacity [176].

The pure neutral exchange of alkaline-earth species for Na^+ ions does not change the concentrations of the species involved in the dissociation of carbonic acid. However, the saturation index is strongly affected. The decreased calcium concentration results in a decrease in the numerical value of $m - 2\,c\,(Ca^{2+})$. Since the $CaCO_3 - H_2CO_3$ equilibrium is now described by the respective curve, the product water is far away from saturation and becomes lime agressive.

6.2.2. *Strongly Acidic Resins in the H^+ Form*

Strongly acidic resins in the H^+ form are normally applied in demineralization processes prior to the elimination of anions by means of anion exchangers. Because of the exchange of practically all cations for H^+ ions, salts are converted to the corresponding mineral acids:

$$\begin{aligned}&\overline{R-SO_3^-H^+}+\\&(Ca^{2+},Mg^{2+},Na^+,SO_4^{2-},Cl^-,HCO_3^-)\\&\rightleftharpoons\overline{R-SO_3^-(Ca^{2+},Mg^{2+},Na^+)}+\\&H_2SO_4,HCl,H_2CO_3\end{aligned}\qquad(6.18)$$

Regeneration is carried out by using HCl or H_2SO_4. However, with respect to the precipitation of $CaSO_4$, the concentration of sulfuric acid used for regeneration must be relatively low. As a consequence, the regenerant volume is greater. The amount of acid that must be applied depends on the tolerable leakage, mainly of sodium, during the service cycle.

As long as no carbon dioxide is degassed from the water, TIC remains constant. Therefore, the development of the state of water follows a straight line with a gradient equal to –1. The final state depends on the concentration of strong acids (Figure 23).

Figure 23. Change of chemical state of water during cation exchange with strongly or weakly acidic resins in the hydrogen form. The raw water composition in Figure 22 was assumed.

R = Raw water; P_w = Product water after weakly acidic resin; P_s = Product water after strongly acidic resin

6.2.3. *Weakly Acidic Resins in the Hydrogen Form*

If weakly acidic resins in the hydrogen form are allowed to come in contact with natural water, a so-called reaction-coupled exchange occurs: protons from carboxylic groups of the resin react with anions of weak acids, normally HCO_3^- and CO_3^{2-}. Thus, nondissociated carbonic acid is formed. To maintain electroneutrality, the resin adsorbs cations. Corresponding to their stronger affinity, alkaline-earth ions are mainly eliminated; Na^+ and K^+ are exchanged only if the raw alkalinity exceeds the sum of the equivalents of calcium and magnesium ions. With respect to the simultaneous elimination of alkaline-earth ions and of alkalinity, the process — called *softening with dealkalization* — represents a partial demineralization [176].

The process can be written as

$$\begin{aligned}&\overline{R-COOH}+\\&(Ca^{2+},Mg^{2+},Na^+,SO_4^{2-},Cl^-,HCO_3^-)\\&\rightleftharpoons\overline{R-COO^-(Ca^{2+},Mg^{2+})}\\&+(Na^+,H_2SO_4,HCl,H_2CO_3)\end{aligned}\qquad(6.19)$$

Softening with dealkalization can be applied as the first step during demineralization to eliminate a substantial part of the total salinity. Furthermore, it can be combined with a subsequent softening using a strongly acidic resin in the Na^+ form. In this way, cooling water or feed water for low-pressure boilers can be produced. Finally, softening with dealkalization also has been proposed to soften drinking water.

Strong acids must be used for complete conversion of the resin to the hydrogen form during regeneration. Since the functional groups show a very strong preference for protons, only slightly more than the theoretical amount of acid has to be applied. Furthermore, the acid need not be concentrated or very pure. Weakly acidic resins can also be regenerated by using weak acids (i.e., citric or carbonic acid). In the latter case, however, only partial conversion to the hydrogen form is achieved [179-182].

During the combined softening – dealkalization with weakly acidic resins, the chemical state of water changes along a line with a gradient of –1 until $m = 0$ and pH $\simeq$ 4, provided no CO_2 degasses. In practice, however, acrylic resins split part of the neutral salts. Therefore, the final m value is slightly negative at a pH of ca. 3.5. Figure 23 demonstrates the change of state of water for the application of strongly acidic and weakly acidic resins in the hydrogen form.

6.3. Anion-Exchange Processes

6.3.1. *Strongly Basic Resins in the Cl^- Form*

Strongly basic resins in the Cl^- form allow the elimination of troublesome anionic impurities such as NO_3^- and SO_4^{2-}. They have also been proposed and applied to the elimination of chromate, arsenate, and selenate [183-185]. In contact with

natural water, SO_4^{2-} and NO_3^- are exchanged easily. However, an uptake of nonpreferred species such as HCO_3^- by the resin also results:

$$\overline{R-N(CH_3)_3^+Cl^-} + (SO_4^{2-}, NO_3^-, HCO_3^-) \rightleftharpoons \overline{R-N(CH_3)_3^+(SO_4^{2-}, NO_3^-, HCO_3^-)} + Cl^- \quad (6.20)$$

Corresponding to the sequence of selectivity, subsequent zones with different resin loading are formed in filters. The boundaries between these regions pass the filter as traveling waves. Each nonpreferred species is replaced by stronger preferred ones and dumped out of the filter. As a consequence, the effluent undergoes variations mainly in HCO_3^- concentration. Initially, part of the bicarbonate is eliminated from water, accompanied by a decrease of pH. However, during a later part of the filter operation, bound bicarbonate species are replaced in the resin, which leads to higher concentration and pH values in the effluent than in the feed. These variations depend strongly on the individual properties of the resin and the composition of raw water. Therefore, this cannot be generalized. Consequently, the exchange of anions for Cl^- ions cannot be demonstrated graphically.

Strongly basic resins in the chloride form are frequently used to eliminate nitrate ions from drinking water. Unfortunately, standard strongly basic resins exhibit a marked preference for sulfate species. To decrease the predominant uptake of nonhazardous sulfate ions, so-called *nitrate-selective resins* have been developed. These are strongly basic resins of type I with ethyl or butyl instead of methyl groups [186], [187].

Apart from acting as ion exchangers the resins can also be used as adsorbents for organic matter such as humic or fulvic acids. For normal anion-exchange processes, regeneration is carried out by means of 4 – 8 % brine solution. To force the uptake of nonpreferred Cl^- ions, substantial amounts of brine in excess of the stoichiometric quantity are required [176]. These scavenger resins are regenerated by using alkaline brine solution.

6.3.2. *Strongly Basic Resins in the OH^- Form*

Strongly basic resins in the OH^- form replace all anions with OH^- ions. Normally, OH^- loaded resins are applied almost exclusively during demineralization in combination with a strongly acidic cation exchanger, either in subsequent filters or in mixed beds. If the feed water for the basic resin is the effluent of a strongly acidic resin, the anions of strong acids are exchanged for OH^- and water molecules are generated:

$$\overline{R-N(CH_3)_3^+OH^-} + (H^+, SO_4^{2-}, NO_3^-, Cl^-, H_2CO_3) \rightleftharpoons \overline{R-N(CH_3)_3^+(SO_4^{2-}, NO_3^-, Cl^-, HCO_3^-)} + H_2O \quad (6.21)$$

Because of the high degree of protonation of nitrogen atoms in quaternary ammonium groups even at relatively high pH, these resins are also capable of removing nondissociated weak acids such as carbonic acid or silica according to

$$\overline{R-N(CH_3)_3^+OH^-} + SiO_2 \cdot H_2O \rightleftharpoons \overline{R-N(CH_3)_3^+HSiO_3^-} + H_2O \quad (6.22)$$

Regeneration is carried out by means of 4 – 8 % aqueous NaOH solutions. Because of the weak affinity of the resins for OH^-, the regenerant solution must be of high purity.

In a graphical representation the uptake of anions of strong acids and of H_2CO_3 can be subdivided into two parts: (1) During the elimination of SO_4^{2-}, NO_3^-, and Cl^-, no change in TIC occurs. Therefore, the state changes along a line with TIC = constant until $m = 0$. (2) During the sorption of carbonic acid, the state changes along the ordinate toward $p = 0$. The real development runs as a superposition of both parts on an arbitrary line between the states of the feed and of the product water (Fig. 24, curve a). The elimination of silica cannot be represented in such a diagram.

Figure 24. Change of chemical state of water during exchange of anions for OH^- (curve a) and for HCO_3^- ions (curve b). The raw water composition in Figure 22 was assumed.

R = Raw water; P = Product water; P′ = (Hypothetical) state of product water without precipitation of $CaCO_3$

6.3.3. *Strongly Basic Resins in the HCO_3^- Form*

Strongly basic resins of the HCO_3^- form exchange all anions for HCO_3^- ions:

$$\overline{R-N(CH_3)_3^+HCO_3^-} + (H^+, SO_4^{2-}, NO_3^-, Cl^-, H_2CO_3) \rightleftharpoons \overline{R-N(CH_3)_3^+(SO_4^{2-}, NO_3^-, Cl^-)} + HCO_3^- \quad (6.23)$$

According to Equation (6.23), anion exchangers in the bicarbonate form may be used to eliminate nitrate from drinking water [188], [189]. However, this kind of exchange can be applied only if the concentration of calcium ions is low. Otherwise, the

solubility product of calcium carbonate is exceeded, yielding uncontrollable precipitation of solid $CaCO_3$. Apart from their application as single exchangers, anion exchangers in the bicarbonate form are used in the Desal and Carix processes [190-192].

Regeneration can be carried out either in a single step by using $NaHCO_3$ or H_2CO_3 (+ MgO) or in two subsequent steps by means of NaOH or aqueous NH_3 and CO_2 [189], [193].

During the exchange of anions for HCO_3^- species, an increase of *m* at constant *p* is encountered. Thus, the state moves on a horizontal line. If the theoretical end point lay beyond the saturation curve, $CaCO_3$ would be precipitated, which limits the further increase of *m*. The state of the product water is then represented by the intersection of a line *p* = constant with the saturation curve (see Fig. 24, curve b).

6.3.4. *Weakly Basic Resins*

In neutral or alkaline media, weakly basic resins in the free-base form are only weakly protonated. Because of the corresponding lack of positive charges they cannot act as anion exchangers. As a consequnce, they can adsorb an-ions only from acidic media with pH <6. These resins are therefore able to eliminate strong acids from the effluent of a strongly acidic cation exchanger in the H^+ form. The uptake of carbonic acid by the resin is, however, negligible, with the exception of acrylic weakly basic resins. The exchange, which can also be classified as an adsorption of acids, can be represented as

$$\begin{aligned}&\overline{R-NR_2'\cdot H_2O}+(H^+,SO_4^{2-},NO_3^-,Cl^-,H_2CO_3)\\&\rightleftharpoons\overline{R-NR_2'H+(SO_4^{2-},NO_3^-,Cl^-)}\\&+H_2CO_3+H_2O\end{aligned}\qquad(6.24)$$

Regeneration requires alkaline solutions such as NaOH or aqueous NH_3. As with weakly acidic resins, the regenerant solution need not be concentrated or extremely pure. Because of the pH-dependent protonation of the amino groups, regeneration requires only slightly more than the theoretical amount. Like strongly basic exchangers, weakly basic resins can be used to remove humic substances.

The development of the chemical state of water treated with weakly basic resins closely resembles that of water treated with strongly basic resins. The negative *m* value of the feed water is increased until *m* = 0. Thus, the development follows a straight line with TIC = constant. The uptake of small amounts of carbonic acid by the resin leads to a decrease in TIC according to individual resin properties.

Figure 25 demonstrates the advantage of degassing CO_2 only after using the weakly basic resin. Because of the leakage of sodium in cation exchange, the *m* alkalinity of the effluent of a weakly basic resin becomes slightly positive. As follows from Figure 25, for this case the pH of the product water is high for low CO_2 concentrations and lower at high concentrations. Because of the pH-dependent protonation of the functional group the exchange capacity of the resin is necessarily greater at a high TIC.

Figure 25. Change of chemical state of water during treatment of an acidic solution with a weakly basic resin (no uptake of CO_2). The raw water composition in Figure 22 was assumed.

R = Raw water; P = Product water

6.4. Combined Processes

6.4.1. *Demineralization*

The simplest form of demineralization of groundwater (e.g., for boiler feed water) consists of the subsequent application of a strongly acidic resin in the H^+ form and a strongly or weakly basic resin in the OH^- form or free-base form, respectively. Depending on the composition and quality of the fresh water to be treated and the desired product water quality, a weakly acidic resin can also be applied in the first step followed by a strongly or weakly basic anion-exchange resins [176]. This process design also saves regeneration costs. The development of the state of the water can be compiled easily from the previous sections.

Figure 26 demonstrates changes of the state of water. Furthermore, it clearly shows the advantages of using weak electrolyte resins for the removal of alkalinity and strong acids, and of efficient degassing prior to the use of a strongly basic resin.

Figure 26. Change of chemical state of water during demineralization by combined application of weakly and strongly acidic resins, a weakly basic resin, a degassing step, and a strongly basic resin. The raw water composition in Figure 22 was assumed

R = Raw water; P = Product water; I_1 – I_4 = Intermediate states; – – – Equilibrium with atmospheric CO_2

For the demineralization of brackish water, other concepts have been proposed, for example, the Desal process [189], [190] (⟶ Ion Exchangers). The process is unique because of its exclusive use of weak electrolyte resins. Its key is the application of an acrylic weakly basic resin, which in contrast to styrene-based resins can adsorb HCO_3^- ions. In the first step, an anion exchanger converts all the salts to salts of carbonic acids, which can be split by a weakly acidic resin applied in the second step. Carbon dioxide evolved in this step is used for conversion of a second weakly basic resin from the free base to the HCO_3^- form. Despite its advantages, the Desal process has never been used on a pilot or technical scale.

6.4.2. *Partial Demineralization*

Partial demineralization is achieved either by the application of a sequence of (completely regenerated) exchange resins not allowing full demineralization or by the use of incompletely regenerated resins. The simplest partial demineralization using completely regenerated exchangers involves softening with dealkalization by using a weakly acidic resin in the hydrogen form (see Section Weakly Acidic Resins in the Hydrogen Form). Another example is the combination of a weakly acidic resin in the hydrogen form and a strongly acidic resin in the Na^+ form. The change of the state of the water can be derived easily from the corresponding plots.

Among the processes using incompletely regenerated resins, the Sirotherm and Carix processes (⟶ Ion Exchangers) are the most important.

The Sirotherm process, also developed for the treatment of brackish water, uses a resin with a mixed weakly acidic and weakly basic functionality [194], [195]:

$$\overline{R-COOH} + \overline{R-NR_2'} + NaCl \rightleftharpoons \overline{R-COO^-Na^+} + \overline{R-NH^+R_2'Cl^-} + H_2O \qquad (6.24)$$

The service cycle runs at ambient temperature; regeneration, however, is carried out by means of hot water, thus making use of the temperature-dependent dissociation of water. Since the treatment of NaCl solutions does not influence carbonate balance, no change in chemical state occurs as defined in Section Characterization of the Chemical State of Water.

The Carix process consists of the combined application of a weakly acidic resin in the free-acid form and of a strongly basic resin in the HCO_3^- form. Both resins are used as mixed beds. In the service cycle, the resin mixture replaces neutral salts with carbonic acid. The resins are regenerated as a mixture by using carbonic acid. The process is applied for partial demineralization of drinking water. The simplified formal representation of the process is [192]:

$$\begin{matrix} \overline{R-COOH} \\ \\ \overline{R^+-HCO_3^-} \end{matrix} + (Ca^{2+} + SO_4^{2-}) \rightleftharpoons \begin{matrix} \overline{R-COO^-(Ca^{2+})} \\ \\ R^+-(SO_4^{2-}) \end{matrix} + (H_2CO_3) \qquad (6.25)$$

In the regeneration step the exchange capacity generated on the cation exchanger is greater than that on the anion exchanger. As a consequence, the elimination of neutral salts in the service cycle is accompanied by a softening or dealkalization by the cation exchanger.

By using ion-exchange resins completely converted to the hydrogen and HCO_3^- forms, process development can be divided into three steps. First, the cation exchanger reduces the *m* alkalinity to about zero, accompanied by a corresponding increase in concentration of dissolved carbon dioxide; second, the anion exchanger replaces anions of strong acids with HCO_3^- species to yield an increase of *m* alkalinity. Thus, the cation exchanger can again replace cations by protons (Fig. 27). Because of the limited efficiency of carbonic acid, only partial regeneration of both resins is achieved. As a consequence, the exchange on both resins remains incomplete, yielding considerable leakage of both anions and cations. The possible development of the chemical state of the water is plotted in Figure 27.

Figure 27. Development of the chemical state of water in the Carix process. The raw water composition in Figure 22 was assumed.

R = Raw water; P = Product water; P′ = Hypothetical product water; – – – = Hypothetical development with completely regenerated resins; ——— = Development under realistic conditions

7. Flocculation

Martin Jekel

7.1. Introduction

Most surface waters contain finely dispersed substances that cannot be separated completely by simple sedimentation or rapid filtration. These dispersed particles are responsible for the turbidity of water and may consist of minerals such as silica and clays, algae cells, bacteria, viruses, organic detritus, or insoluble pollutants [196]. In groundwater, particles can be formed by a preceding precipitation (e.g., lime precipitation for hardness removal) or by oxidation of iron(II) and manganese ions. The finely dispersed particles can be aggregated to form removable flocs by flocculation techniques using suitable

chemicals known as coagulants and flocculants.

The aggregates formed can be removed to a wide degree by subsequent separation processes such as sedimentation, flotation, or filtration. In the production of high-quality water such as drinking water, sedimentation and flotation usually are followed by rapid filtration, while direct filtration of flocs (see Chap. Filtration) is limited to raw water with low suspended solids and coagulant demand.

The removal of *particulate substances* is usually the primary objective of flocculation, but important cases exist in which *dissolved* inorganic and organic substances must be removed effectively by coagulants and flocculants via precipitation, coprecipitation, or adsorption onto the flocs. Examples are phosphates, some heavy metals, or dissolved organic substances of natural or anthropogenic origin. In view of the new standards for lower concentrations of organic substances in drinking water, the removal of DOC has become a major task in water treatment, especially in raw water colored by natural humic substances or having a high DOC [197].

7.2. Definitions

Scientific and technical terms that are used frequently in flocculation are listed and explained below [198-201]:

Colloids are particles with diameters in the range of 0.001 – 1 µm. They do not settle, and they cause turbidity. Their high specific surface areas induce important interfacial forces and phenomena between the colloid particles.

Suspended particles have diameters >1 µm and are detected under a light microscope. They may be removed by settling if their density is greater than that of water.

Aggregation denotes the general process of forming larger flocs from primary particles.

Stabilization. Colloidal and suspended particles can be stabilized against aggregation. Stabilization is caused by van der Waals attractive forces, by the electrostatic surface charge of the particles, by an adsorbed layer of polymers, or by forces of hydration. Most important in aqueous systems are the negative surface charges formed by the dissociation of protons from hydroxyl functions belonging to silica groups or from acidic carboxylic functions [196], [198], [199].

Destabilization. Stable particles are rendered unstable through neutralization of their negative surface charges by adsorption of positively charged coagulants.

Coagulation refers to (1) the reduction or elimination of electrostatic repulsion forces between particles via addition of certain coagulants, and (2) in technical terms, the first phase of floc formation after chemical mixing and destabilization, but before dosing of flocculants (see below) [199].

Flocculation. (1) Flocculation is the mechanism of floc aggregation by high molar mass polymers that adsorb on the particles and form bridges between them. (2) In water treatment, flocculation is the phase of formation of large flocs by addition of a secondary chemical (after addition of the coagulant) called a flocculant or flocculant aid [199]. (3) The term can be used for the entire water treatment process (coagulation plus flocculation), as in this chapter. In English-speaking countries, the terminology “coagulation and flocculation” is also used frequently to describe this process.

Coagulants are chemicals used for destabilization in the first phase of floc formation. Most common are the salts of Al^{3+} and Fe^{3+} ions; sometimes, organic cationic polymers are used.

Flocculants designate chemicals used to improve the formation of larger flocs. Flocculants are high molar mass water-soluble polymers. Flocculant aid or coagulant aid is used as a synonym.

Precipitation is the formation of insoluble substances from dissolved matter and the chemicals added. The important coagulants Al^{3+} and Fe^{3+} salts can precipitate as hydroxides in the neutral pH region and are thus removed from water.

Coprecipitation is the inclusion of dissolved or particulate substances into a precipitate (e.g., of aluminum or iron(III) hydroxide). Particles are then aggregated by the important *sweep coagulation mechanism*, with the amorphous, gelatinous hydroxide flocs acting as particle collectors.

7.3. Chemicals Used in Coagulation and Flocculation

7.3.1. *Inorganic Chemicals (* ⟶ Flocculants – Inorganic Flocculants*)*

The most important coagulants in water treatment are the salts of iron(III) and aluminum ions, available in various commercial forms and purities. Iron(III) chloride or aluminum sulfate (alum) is used frequently because of low cost. Mixed coagulants are also available, especially for applications in wastewater treatment. These coagulants dissolve readily in water, and the metal ions form hexaquo complexes, $Me(H_2O)_6^{3+}$, which are acidic species and give up protons [202].

The aquo complexes are stable below pH 3 – 4 (Al^{3+}) and 1 – 2 (Fe^{3+}). After stepwise formation of hydroxo – aquo complexes with increasing pH, insoluble hydroxides are formed at higher pH (Al^{3+}, pH > 5.5 – 6.0; Fe^{3+}, pH > 4.5 – 5) as voluminous, amorphous flocs. The residual concentrations of dissolved metal ions are well below the drinking water standards of 0.2 mg/L for Fe and Al. The $Al(OH)_3$ dissolves as aluminate $[Al(OH)_4^-$ at pH > 7.5 – 8.0, which must be avoided in water treatment [203]; $Fe(OH)_3$ redissolves at pH > 10 – 11 to form $Fe(OH)_4^-$.

The cationic partially hydrolyzed species present in a slightly acidic medium can condense to form polymeric products with a high positive charge. Various oligomeric and polymeric products are known [e.g., $Al_{13}(OH)_{32}^{7+}$ and $Fe_3(OH)_4^{5+}$]. For more

details on hydrolysis and condensation reactions, see [202]. Cationic aluminum polymers are available as commercial products or can be produced by partial hydrolysis and polymerization. These coagulants are usually called polyaluminum salts, but their composition and degree of hydrolysis vary widely.

Iron(III) and aluminum salts exhibit two distinctly different mechanisms in particle aggregation [204]:

1. Cationic polymeric species adsorb on negatively charged particles and neutralize them at an optimum dosage (charge and neutralization). Overdosing leads to restabilization because of charge reversal.
2. Insoluble hydroxides precipitate and enmesh the particles by the sweep coagulation mechanism. Optimum coagulation is achieved under conditions of maximum precipitation of the hydroxides. The nature and concentration of particles have no effect.

The sweep coagulation process is the dominant mechanism in most cases, whereas charge neutralization may be important in the coagulation of algae, humic colloids, or more concentrated suspensions and at a pH of <6.0 – 6.5.

The optimum dosages of Al^{3+} or Fe^{3+} may vary with water source and, because of frequent changes in raw water quality, even in the same plant within a few hours. The typical dosages given below are a preliminary guide for frequent cases:

1. Treatment plants for river water with settling: 0.05 – 0.2 mol/m^3 Me^{3+}
2. Treatment plants for lake and impounded water with direct or in-line filtration: 0.01 – 0.1 mol/m^3 Me^{3+}
3. Treatment plants for color and DOC removal: 0.01 – 0.05 mmol Me^{3+} per milligram DOC; optimum pH values for Al^{3+}: 5.5 – 6.5; for Fe^{3+}: 4.5 – 6 [205], [206]

Laboratory tests are usually performed to find the most suitable coagulation conditions before adjusting dosages in the plant.

Other inorganic chemicals are much less common, such as “activated silica,” a polymeric flocculant, or $Mg(OH)_2$, formed at pH >10.5 [200].

7.3.2. *Organic Chemicals (* ⟶ Flocculants – Natural Organic Flocculants, ⟶ Flocculants – Chemical Structure*)*

Organic substances added in flocculation are linear, water-soluble polymeres (synthetic, natural, or modified natural polymers) with mean molar masses in the range of 10^4 – 10^7 g/mol. The following monomers are included [200]:

Acrylamide (nonionic), acrylic acid (anionic), *N,N*-(dimethylaminopropyl)methacrylate (cationic), and ethyleneamine (cationic).

The resulting polymers can be nonionic, cationic, or anionic; the charge density can vary from low to very high, depending on copolymer composition. The molecular diameter of the polymers in solution is 10 – 500 nm.

Most commercial polymers are copolymers, containing at least two monomer types. The monomer content of these products is limited to 0.05 – 0.1 % if they are used in drinking water treatment [207].

Highly charged cationic polymers can be applied as coagulants, instead of Al^{3+} and Fe^{3+} salts because of their effective charge neutralization mechanism at optimum dosage [208]. The dosages required can be rather high (1 – 10 g/m^3).

High molar mass polymers with low to medium charge densities are flocculants, acting by the adsorption-bridging mechanism [198]. Typical dosages are in the range of 0.05 – 1.0 mg/L, and the polymer should be added at least 30 s after addition of the metal salts. Flocs formed with the aid of these polymers are larger, are more resistant to erosive and destructive forces, and settle faster.

In addition to synthetic polymers, natural or modified natural polymers such as starch, modified starch, or alginates can be used. Since natural polymers tend to be less effective, are unstable, and may support bacterial growth, they must be applied with more care.

7.4. Kinetics of Aggregation

The particle transport processes necessary for particle collisions are usually slower than mixing, chemical reactions (e.g., hydrolysis), adsorption, and destabilization. The kinetic rate of aggregation is thus determined by the particle collision rate, which itself depends on three basic transport processes [198], [209].

Particle diffusion is based on Brownian movement and dominates in concentrated colloidal systems if the particle diameter is <0.5 – 1 µm. This *perikinetic coagulation* is probably not important in water treatment or is limited to the first short phase until microflocs appear with diameters >1 µm.

Hydrodynamic shear gradients imposed by stirring or turbulent flow are responsible for different particle velocities. This important collision mechanism (*orthokinetic coagulation*) can be described for the initial period by

$$\ln N/N_0 = -4/\pi \cdot \alpha \cdot \phi \cdot \overline{G} \cdot t \qquad (7.1)$$

where N and N_0 are the total particle concentrations at time t or $t = 0$; α is the collision efficiency factor; $\bar{G}$ is the mean shear gradient (s^{-1}); Φ is the volume concentration of solids; and t is time.

The collision efficiency factor depends on the extent of destabilization of the particles (chemical factor), while $\bar{G}$ represents

shear conditions. The mean value $\bar{G}$ is used for turbulent conditions and can be calculated [198] according to the following: For back-mix reactors

$$\overline{G} = \left(\frac{P}{\eta \cdot V}\right)^{1/2} \tag{7.2}$$

where *P* is the power input of stirrer; *V* the reactor volume; and η the dynamic viscosity.

For pipes and channels

$$\overline{G} = \left(\frac{\Delta p \cdot v}{l \cdot \eta}\right)^{1/2} \tag{7.3}$$

where Δp is the pressure loss; *v* the flow rate; *l* the length of the pipe; and η the dynamic viscosity.

The orthokinetic equation is not longer valid if larger flocs are formed and destroyed again. In this case, the formula must be extended by a floc destruction term [210], describing the fact that larger flocs are formed at low $\bar{G}$ values, while high $\bar{G}$ values induce smaller flocs. In designing flocculation reactors, the use of two or more reactors can reduce overall reactor volume. The first reactor is operated at high $\bar{G}$ values for high collision rates but small flocs, whereas the second reactor is needed to produce large flocs at low $\bar{G}$ values (see Section Process Technology for Coagulation and Flocculation).

The final flocs are separated by either settling, flotation, or filtration, whereby the different floc velocities induce further collisions and floc growth. This third transport process is significant in settling and flotation tanks.

7.5. Process Technology for Coagulation and Flocculation

The major process steps in coagulation and flocculation are listed in Table 27. Steps 1 and 2 are physically different processes but are quite rapid and usually occur in the same reactor, the rapid mix system. Steps 3 and 4 are performed in one, two, or more reactors, depending on plant design.

Table 27. Process steps for coagulation and flocculation systems

Step	Task
Dosing of coagulants and rapid mixing	homogeneous distribution of chemicals
Destabilization	adsorption of coagulants on colloids and suspended particles, precipitation of dissolved substances
Aggregation to microflocs (coagulation)	rapid formation of small flocs from destabilized particles in high shear gradients, without flocculants (polymers)
Aggregation to macroflocs (flocculation)	formation of removable large flocs, with or without a flocculant (polymer)

7.5.1. *Dosing*

Coagulants and flocculants are generally prepared as a stock solution or delivered as a concentrated solution. Some restrictions exist on the concentration of stock solutions and their predilution before dosing. *Iron(III) and aluminum salts* may start to precipitate or hydrolyze at concentrations <1 % (Fe, Al) and pH values >1 – 2. Polymeric aluminum salts should be diluted only to the ratios given by the producer. All metal salts are acidic or alkaline solutions and require safety precautions. Iron(III) salts are especially corrosive.

Organic polymer solutions exhibit high viscosities at concentrations >0.2 – 0.5 %, depending on their molar mass. Dissolution sometimes requires several hours, and the stock solution may not be highly turbulent because of loss of efficiency and should be stored for only a limited time.

National and upcoming international standards exist regarding the purity of all applied chemicals to avoid secondary pollution in the finished drinking water. Cationic polymers, especially, are not approved for use in several countries because their risks are unknown.

7.5.2. *Rapid Mixing*

The small flow of a dissolved coagulant and flocculant must be distributed rapidly in the large water flow by suitable reactors. Efficient, rapid mixing is very important for destabilization of colloids. The present state of knowledge and technology is summarized in [211]. Rapid mixing reactors can be designed as plug-flow or back-mix systems. The latter apparently have some deficiencies in terms of coagulation, because the coagulant species may not be transported evenly to all particles in a short time. Mixing studies indicate that the metal salts should be mixed completely within 0.1 – 1 s, which may be difficult to achieve in large plants [211].

Possible rapid mixers are listed in Table 28. If polymeric flocculants are dosed after the primary coagulants (usually metal salts), the retention time between dosing points should be at least 30 s or more to avoid a higher polymer demand. Polymers should not be mixed with excessive intensity to limit microfloc destruction and polymer breakage.

Table 28. Rapid mixer and destabilization units

Basic type	Examples, characteristics
Pipes and channels (plug flow)	without internals, with orifices or in-line mixers
	with pipe restrictions and expansions
	with static mixers
	with high-speed injection
Stirred vessels (back mix)	detention time 10 – 120 s
	shear gradient >1000 s^{-1}
	special design to control back mixing and retention time distribution
	mixing energy can be varied
Turbulent zones	before, at, or after pumps
	hydraulic jumps
	venturi tubes
	weirs with overfall

7.5.3. *Reactors for Floc Formation*

A variety of reactors for aggregation exist in water treatment, depending on historical developments, national regulations and experience, and the technical solutions of plant designers. The basic principles are as follows [199]:

1. Stirred tanks (back-mix reactors)
2. Pipes (plug-flow reactors)
3. Static systems (channels with baffles, plug flow, and some back mixing)
4. Sludge contact systems (sludge recycling or retention in flocculators)
5. One or more of these reactors in series

Stirred tanks are used widely and allow adjustment of the mean shear gradient independently of plant flow. The tanks are designed in rectangular form or as round vessels with baffles. Retention times at nominal flow are generally between 10 and 30 min (total); longer times are needed if only one reactor is used. The required retention time is lower (2 – 10 min) in direct filtration plants. The mean shear gradients adjusted by the stirrer speed are in the range of 10 – 100 s^{-1}. In two or more sequential reactors, the $\bar{G}$ value declines typically from ca. 100 s^{-1} to 10 – 30 s^{-1}. If polymeric flocculants are added, the final shear gradient can be higher, ca. 25 – 50 s^{-1}, because of more rigid flocs. Inlets and outlets must be arranged properly to avoid short-circuits. The stirrers used are mostly of the blade or grid type, and stirrer speed should be variable to optimize floc formation under various conditions of raw water and flow.

Flocculation in pipes [212] offers the possibility of using existing piping and saving space, but the efficiency of flocculation depends on flow rate. At a low flow rate, the kinetics of aggregation are slower and solids may settle, while at high flow the flocs tend to be destroyed. Polymeric flocculants are required, and the pipe design should avoid narrow bends and other high turbulence. Pipe lengths required are 20 – 50 m, corresponding to ca. 0.5 – 2-min detention time.

Static Channel Flocculators. Similar reactor characteristics are found in static channel flocculators equipped with baffles to induce back mixing and establish shear gradients by the head loss. These systems are in wide use in developing countries because of their simple design and construction [213], [214]. The channels are usually arranged one by one in flat, rectangular tanks, requiring more surface area compared to other flocculators. Easy cleaning of the channel bottom is essential. The width of the channels may be constant or increasing in the direction of flow to lower the $\bar{G}$ value. Total detention times are generally about 20 – 40 min. Design parameters and examples are given in [214].

Sludge contact systems use the positive kinetic effect of high volume concentrations of suspended solids (see Φ in Eq. 7.1) by retaining the flocs in reactors by various methods. Besides more rapid floc formation, denser and larger flocs are formed, which settle faster. Sludge contact is established only in combination with sedimentation. Basically, two techniques are applied:

1. Recycling of settled sludge to the flocculators (stirred tanks)
2. Sludge blanket systems in upflow tanks with vertical or inclined walls

A *sludge blanket* is established when the flocs have a settling rate equal to the upflow rate. Raw water enters the bottom after rapid mixing via a pipe system, and destabilized particles are captured by the large flocs of the blanket. Excess sludge is removed via sludge hoppers. Sludge blanket reactors need an extended period of startup and are somewhat sensitive to rapid flow increase. They have advantages for low-turbidity and algae-laden raw water. Their upflow rate is in the range of 2 – 4 m/h. A commercial system uses a pulsating raw water flow [215]. Equipped with parallel plates, a more recent version can operate at an 8 – 12-m/h upflow rate. New flocculators use a stirred upflow tank to form pellet-like flocs of high density [216].

7.5.4. *Integrated Flocculation Systems*

Because of the great variety of reactors and floc separators employed only a few examples are shown here. *Classic process schemes* including settling are depicted in Figures 28 and 29. The total detention time is 2 – 4 h, and the systems are most suitable for treatment of river water with a variable content of mineral solids. The settler itself can be designed as a rectangular (Fig. 28) or a circular (Fig. 29) tank with a circular flocculator in the inner section [200]. Settled sludge may be recycled to the flocculators by a pump.

Figure 28. Rectangular settlers

a) Rapid mixing; b) Flocculator; c) Sedimentation

Figure 29. Circular system

The introduction of *parallel plates* or tubes into sedimentation units can reduce retention times. Such a system is shown in Figure 30, including coagulant mixing (a), sludge recycle, and polymer mixing (b); two stirred flocculators (c); parallel plate settlers (d); and a sludge thickener (e) below the plates. The total detention time is only 30 min at full capacity [200], [217].

Figure 30. Process scheme of treatment plant with multiple stirring, parallel plate settler, and thickener

a) Coagulant mixing; b) Polymer mixing; c) Stirred flocculator; d) Parallel plate settler; e) Sludge thickener

Direct filtration of flocculated water can be employed for low-turbidity raw water from lakes and dams. The flocs can be quite small (microflocs) to be filtered off in dual- or triple-media filters, at rates of 10 – 15 m/h. An example is shown in Figure 31 [218].

Figure 31. Direct filtration plant with three-layer filter

a) Rapid mixing; b) Flocculator; c) Three-layer filter

Flotation is a feasible floc removal process for low-density flocs, formed in colored, humic acid water or in algae-laden raw water. The version used mostly is dissolved air flotation (DAF, ⟶ Wastewater), recycling 5 – 10 % of the clarified water, which is saturated with air under a pressure of 5 – 10 bar. The flocculated water and recycled pressurized water are mixed; gas bubbles are formed, attach to the flocs, and cause them to float [219]. This process typically requires less space than classical flocculation processes, no polymers, somewhat shorter flocculation times, and no additives for flotation.

Since the 1970s, the introduction of preozonation before coagulant addition has proved successful to decrease turbidity and increase the removal of algae, to lower coagulant demand, or to extend filter run times in direct filtration [220]. Ozone is applied typically in dosages of 0.5 – 2 mg/L, depending on raw water conditions. Other oxidants such as chlorine or chlorine dioxide are less efficient or are avoided because of the formation of harmful byproducts.

7.5.5. *Operational Aspects*

The selection of suitable coagulants and flocculants and the continuous task of adjusting their dosages to optimum values are based mainly on experience, rule of thumb, and extensive laboratory and pilot-plant testing. The great number of parameters that influence flocculation and the lack of quantitative models require adapted testing procedures. The *jar-test* is the most widely used laboratory test, suitable for conventional plants and chemical selection [198], [199], [221]. Other tests include filtration or batch flotation. Flow-through pilot plants are usually designed according to full-scale systems and allow more experiments, especially regarding hydrodynamic parameters. However, problems occur in scaling-up pilot systems [222] because of different flow patterns. Large-scale plants are therefore often equipped with variable-speed stirrers or changeable reactor geometry to adjust the reactors to flow variation. On-line control and dosage adjustment have been implemented sucessfully in some plants in the 1980s, based on novel techniques and sensor systems [223], but their application require careful evaluation.

8. Filtration

Rolf Gimbel

8.1. Introduction

In this chapter, only the elimination of turbidity-causing solids (colloidal or finely suspended particles) by filtration is described. Consequently, this is clearly distinguished from filtration through layers of activated carbon (see Chap. Adsorption Processes in Water Treatment) or ion exchangers (see Chap. Ion Exchange), which is used primarily for the removal of fully dissolved water constituents.

Surface Filtration. The removal of turbidity from water can be carried out by using surface filtration (either *cake filtration* or *cross-flow filtration*; see Fig. 32 A and B). In surface filtration, the dimensions of the particulates are greater than the pore size of the filter medium (or of the filter cake possibly already present on it). Therefore, particles are retained because of sieve effects, while water passes through the filter medium under a pressure gradient. Surface filtration is used in many different areas of industry for solid – liquid separation (⟶ Filtration – Washing of Filter Cakes, ⟶ Filtration – Optimal Cycle Time). The liquids treated range from extremely dilute solutions to highly concentrated suspensions or sludge (dewatering). Therefore, a large number of different processes and equipment are available, which operate according to the basic principle of surface filtration. These also include membrane filtration processes (see Chap. Membrane Separation Processes in Water Treatment).

Figure 32. Schematic representation of various types of turbidity filtration

A) Cake filtration; B) Cross-flow filtration; C) Deep-bed filtration

a) Suspension flux; b) Filter medium or filter layer; c) Filtrate flux; d) Filter cake

Deep-Bed Filtration. In the treatment of wastewater and drinking water and the production of cooling and process water, by far the predominant amount of water is subjected to deep-bed or depth filtration to eliminate turbidity (see Fig. 32 C) (⟶ Filtration – Deliquoring of Filter Cakes). In contrast to surface filtration, particles are retained in the interior (i.e., trapped in the depths) of a porous filter layer, which usually consists of a bed of granular material. To maintain the depth effect of filters of this type, the particulates to be separated must be considerably smaller than the pore size of the filter layer. Otherwise, the top part of this layer changes to cake filtration after a very short filtration time, resulting in an excessive pressure drop in the uppermost filter layer.

Deep-bed filtration is used especially for the purification of liquids having very low solid concentrations or when the filtrate is required in larger quantities and with a high purity (i.e., practically free of turbidity). For this reason, deep-bed filtration is applied mainly in the aforementioned areas of water technology. A volume concentration of solids of <0.05 % can serve as a rough upper limit for the economically meaningful use of depth filters.

To achieve separation, particles must be transported to the surface of the filter material by various transport mechanisms in the interior of the depth filter. At the surface, contact between filter material and particles occurs. In a second step, sufficiently stable adhesion of particles to the filter material must take place. The entire separation process is very complex and can vary greatly depending on application. This variability is due to the complicated flow conditions in the filter layer and to the large range of properties of normally used filter materials. Moreover, the turbidity-causing solids to be separated are diverse and can range from solid mineral particles to particulate biomasses, particle agglomerates, and hydroxide flocs (see Section Inorganic Chemicals) of very low shear strength. Finally, dissolved inorganic and organic water constituents (including polymeric filter aids) greatly influence particle separation. In addition, biological processes can occur.

The design and mode of operation of depth filters are as diverse as the factors influencing deep-bed filtration. Filters can be divided into different groups according to the typical filtration rate in each case (water volume per unit time and total filter cross-sectional area). These groups are discussed in detail below. Today, *rapid filtration* plays a dominant role in water filtration. With rapid filtration as an example, the separation mechanisms of depth filters, which can also be influenced by appropriate pretreatment processes (flocculation, see Chap. Flocculation), and the possibilities of describing total filter behavior (as a basis for optimal filter design) are discussed.

8.2. Slow Sand Filters

Slow sand filters are operated at relatively low filtration rates of about 0.1 m/h. This type of filtration played a dominant role in the treatment of surface waters for the production of drinking water in the beginning of the 20th century and is of great importance until now. Here, purification processes are very similar to those in natural ground filtration. Apart from mechanical sieve effects and physicochemical deep-bed filtration mechanisms (transport and adhesion processes), microbiological processes are especially important [224-226].

Slow sand filters are usually employed in the form of open basins, which can have a filtration area up to 10 000 m^2. The filters are provided with a suitable drainage system or infiltrate the subsoil directly to artificially recharge groundwater (see Fig. 33). The active filter layer consists of a bed of sand with a depth of 0.5 – 1.5 m and a grain size that can vary from 0.2 to 1 mm. The head of water can reach ca. 1.5 m. A new filter develops its full efficiency only after a so-called “Schmutzdecke” (dirt blanket) has been formed in the uppermost filter layer. This is formed from the retained water constituents by a very complicated combination of diverse physical separation mechanisms and biochemical processes. The “Schmutzdecke” can reach a height of a few centimeters. The purification processes involved in slow sand filtration proceed mainly in this layer.

Figure 33. Schematic representation of slow sand filtration

a) Biological filter layer (Schmutzdecke); b) Fine sand, height 0.8 – 1.5 m; c) Supporting layers, height 0.2 – 0.4 m; d)

Drainage system; e) Outflow controller

Excellent water purification can be achieved with slow sand filters. Not only the finest inorganic particles but also particulate organic substances, especially protozoa, bacteria, and viruses, are retained. In addition, dissolved degradable organic substances can be mineralized and nitrogen compounds oxidized by aerobic biological processes. Moreover, smaller amounts of dissolved interfering substances (e.g., heavy metals) can be retained in the “Schmutzdecke”.

A ripening period of several days is required to form the Schmutzdecke. The length of a filter run (the time between two cleaning steps) is usually some months. At the end of a filter run, the pressure drop in the topmost filter layer is increased to such an extent that the required water throughput can no longer be maintained. In general, the necessary filter regeneration is then carried out by peeling off the uppermost 3 – 5 cm of the filter layer.

The disadvantages of the slow sand filter are a large area requirement and laborious filter regeneration. For this reason, new slow sand filtration plants are rarely built in industrialized countries. In many existing plants, attempts are being made to lengthen the filter run by using appropriate pretreatment processes for turbidity removal (flocculation, sedimentation, rapid filtration).

8.3. Polishing Filters

Polishing filters, which include *precoat, disk*, and *cartridge filters*, are characterized by the relatively small radii of the filter pores (micrometer range) and the shallow depth of the active filter layer (millimeter to centimeter range). In filters of this type, apart from physicochemical transport and adhesion processes, sieve effects on the surface of the filter layer can also be significant, depending on the ratio of the size of suspended particles to pore size. Thus, these filters cannot be regarded as pure depth filters in many cases. In contrast to slow sand filtration, however, biological processes are negligible in polishing filtration. With pressure differences up to several bar, polishing filters can be operated at average filtration rates of about 1 m/h. Depending on the specific application, larger deviations from this average can occur [227].

Precoat Filters. In precoat filters, turbidity removal occurs in a layer of a fine granular or fibrous filter aid having a characteristic size of a few micrometers. This layer has previously been filtered onto a support. The aids employed are mainly aluminum silicate (e.g., perlite) and diatomaceous earths. Other filter aids are also used in some cases. For example, powdered activated carbon or a finely dispersed ion-exchange resin gives not only highly efficient separation of colloidal sustances, but also retention of dissolved organic material or ions [228].

In precoat filtration, depending on the conditions, sieve effects on the surface of the precoat layer can dominate after a relatively short filter run, resulting in clogging of the surface. To prevent this and guarantee sufficient permeability of the resulting filter cake, filter aids are often added continuously to the suspension to be treated. In addition, the filter aids of the precoat layer can be conditioned with suitable polymers in such a way that they exhibit especially favorable properties for turbidity removal. The same polymers used in flocculation and rapid filtration are applied.

Precoat filters are usually available as closed apparatus in which the supports have a space-saving flat or tubular arrangement as far as possible. After a filter run that lasts from hours to days depending on the application, the precoat layer is generally discharged by means of a pressure surge. After renewed precoating, which requires a few minutes, the filter is ready for use again.

Disk and Cartridge Filters. In contrast to precoat filtration, the active filter layer in leaf and cartridge filters need not be built up by a filter aid but is available in a preprepared form. Apart from this characteristic difference, the modes of action and operation of different types of polishing filters are similar. The preprepared filter layers can be made of fabric, fleece, felt, or wound string especially in the case of cartridge filters. Finely porous sintered materials such as fibrous or powdery metals, ceramic materials, and plastics are also used. In many cases, disk and cartridge filters require not only mechanical but also chemical cleaning. Alternatively, filter materials are used only once [229], [230].

Filter Performance. In general, excellent filtrate quality can be achieved with polishing filters. They are used especially in the treatment of boiler feed water and ultrapure water, such as that required in the electronic, chemical, and pharmaceutical industry. In addition, these filters are often employed in smaller drinking water treatment plants, in emergency water supply facilities, and in the treatment of water for swimming pools. Polishing filters are used frequently in the food industry for clarification of beverages. In special cases, filters of this type are also used in wastewater treatment and in the purification of various solutions (e.g., in surface technology).

8.4. Rapid Filters

The term rapid filter is derived from the relatively high filtration rate through the filter, which is on average ca. 10 m/h. Filters of this type consist of a relatively coarse-grained filter material (millimeter range) having a filter bed height of 1 – 2 m. The deposition of particles within the filter layer — which generally acts as a real depth filter — is based primarily on physicochemical transport and adhesion mechanisms, which can also be influenced by biological processes.

In industrialized countries, rapid filtration has the greatest practical importance of all filtration processes used in the treatment of drinking water and industrial water or in advanced wastewater treatment. This importance is attributed not only to the low space requirement as a result of high filter rate, but also to the simple design and mode of operation of rapid filters and to the largely automated filter regeneration in which filter material is backwashed within the filter tank.

8.4.1. *Design*

The active layer of rapid filters consists of a bed of granular materials having an average diameter between 0.5 and 4 mm and a bed height of 0.5 – 2.5 m. If a fine-grained filter material is used, low bed heights are sufficient for good removal

efficiency. However, the disadvantage is that the capacity for the particulate load on the filter is exhausted quickly, which results in a short filter running time. Quartz sand, anthracite, filter coke, activated carbon, or pumice serve as filter materials [228].

The *single-medium* design of a classic rapid filter is represented schematically in Figure 34. It consists of a distributing device for raw water (a), an active filter bed (b), which is to be regarded as homogeneous; and a filter bottom (d), which supports the filter material and allows the evenly distributed passage of filtered water into the clean-water chamber (e). The filter bottom made of steel or reinforced concrete either is equipped with filter nozzles provided with fine slits or is made of special porous components. To guarantee perfect functioning of the elements of the filter bottom, especially if fine filter materials are used, one or several supporting layers (c) are included between the active filter bed and the filter bottom. Each supporting layer has a grain size ca. two to four times coarser than the material above it.

Figure 34. Basic design of a rapid filter

a) Raw water distribution; b) Active filter layer (filter bed); c) Supporting layer; d) Filter bottom; e) Clean water chamber

As a rule, the direction of flow in rapid filters is from the top downward. The filter material should have a particle-size distribution as uniform as possible. Otherwise, fine material becomes concentrated in the top filter layer during filter backwashing. This can result in a change to surface filtration, which leads to an excessive pressure drop. To prevent this effect and distribute particle deposition over the greatest possible bed depth, *dual-media* filters are used frequently (see Fig. 35). In this type, the upper filter layer consists of a relatively coarse material of low density (filter coke in Fig. 35), while the lower layer has a fine grain size and high density. If the grain sizes and densities of the filter materials in the two layers are well suited to each other, this structure remains even after filter backwashing. Because of its large pore size, the upper layer has a high load capacity for particulates, whereas particle retention is not necessarily complete. In comparison, the behavior of the lower layer is the opposite. As a result, especially in the case of high-turbidity loads, longer filter running times can be attained with dual-media filters than with single-medium filters. *Three-media filters* have also been used successfully. Typical examples of the design of multimedia filters are given in Table 29.

Table 29. Exemplary design of multimedia filters [228]

Material	Bed depth, m	Bed weight, kg/m^3	Grain size, mm
Dual-media filters			
Filter coke, pumice, etc.	0.5 – 1.2	500 – 700	1.7 – 2.5
Sand	0.6 – 1.5	1000	0.8 – 1.2
Three-media filters			
Activated carbon	0.3 – 0.6	250 – 350	3.0 – 5.0
Filter coke, etc.	0.6 – 1.2	500 – 750	1.5 – 2.5
Sand	0.5 – 0.8	1000	0.6 – 0.8

Figure 35. Exemplary design of a closed dual-media filter

a) Inlet; b) Outlet; c) Filter bottom; d) Sand; e) Filter coke; f) Water distribution

Figure 35 shows the design of *closed rapid filters* (*pressure filters*). Filters of this type are usually made in the form of cylindrical steel tanks. Filter surfaces up to 50 m^2 are achieved in vertical tanks. Horizontal tanks provide much larger filter surfaces but usually have relatively low bed heights. The usual pressure drops vary between 0.2 and 2 bar at filtration rates of about 5 – 30 m/h.

Open rapid filters (gravity filters) are often used in large plants. The pressure drop occurring in the filter bed must be compensated by a head of water above the bed. The height varies between 0.3 and 3 m of water column (corresponding to a pressure drop of 0.03 – 0.3 bar). Usual filter flow rates are in the range of 3 – 15 m/h. Open filters are usually made in the form of rectangular reinforced concrete tanks. Filter surfaces up to 150 m^2 have been achieved. Apart from the classic type of rapid filter shown here, several special designs exist with upward or horizontal flow through the filter layer. Continuously operated rapid filters are also being used increasingly. The loaded filter material is withdrawn continuously from the bottom and returned at the top after a washing stage [231], [232].

8.4.2. *Areas of Application and Modes of Operation*

In water and wastewater treatment, the different applications of rapid filters can be divided into the following main groups [228].

1. *Separation of Single Particles.*
   Applications of this type can be encountered, e.g., in the removal of turbidity from surface water that is to be used as drinking water and industrial water. The particles are inorganic substances (e.g., clay minerals) and organic particles such as plant cells, algae, or bacteria. Further applications are the separation of $CaCO_3$ particles after a water-softening step and the treatment of boiler feed water and swimming pool water. In all these cases, biological processes are usually of secondary importance.
2. *Separation of Particle Agglomerates and Hydroxide Flocs.*
   If turbidity-causing solids are difficult to filter out as single particles, agglomeration is usually carried out before rapid filtration, or the particles are embedded in iron or aluminum hydroxide flocs by means of a flocculation process. Dissolved substances can also be bound in the flocs (see Section Introduction). Applications of this type are encountered frequently in the production of drinking water and industrial water from surface waters and in advanced wastewater treatment. In the latter, the hydroxide flocs to be separated contain not only turbidity but also colloidal and dissolved phosphorus compounds. Biological processes in the filter can greatly influence turbidity removal, especially in advanced wastewater treatment.
3. *Removal of Iron, Manganese, and Ammonium.*
   In the treatment of groundwater to produce drinking water and industrial water, the rapid filter usually has the task of eliminating divalent iron and manganese ions. These ions must be converted to a separable form by chemical or biochemical oxidation before or during actual filtration. In this widely encountered application of rapid filters, chemical – catalytic as well as biological processes are important. Ammonium can also be eliminated by biochemical oxidation.

In many cases, single-medium filters are sufficient for relatively low levels of turbidity in raw water. For higher-turbidity loads, multimedia filters can be of advantage. The importance of multimedia filters has increased since the 1970s because the *direct filtration process* is often used for economic reasons. In direct filtration, water (without preliminary separation of flocs by sedimentation or flotation) is passed directly through rapid filters after a flocculation stage.

Especially in direct filtration, pretreatment of water is very essential. Apart from the type and amount of flocculant used, the conditions of addition (residence time up to the filter, energy input in the flocculation stage, etc.) are also important. Moreover, the flocculation or filter aids added, which are mostly synthetic, water-soluble polymers, can clearly improve the properties of flocs with regard to filtration. Oxidative pretreatment of raw water (e.g., with ozone) can have a similar effect.

In normal depth filtration, the space between the grains of filter material is filled completely with particulates and water. In *dry filtration,* however, air is passed through the filter bed together with water. This special process can be used in water treatment when the aerobic degradation or oxidation processes proceeding in the filter bed are so intense that a continued supply of oxygen via air is required. This applies, for example, to the treatment of water containing high concentrations of ammonium or iron. Dry filtration is usually operated as a preliminary stage in normal rapid filtration because turbidity retention in the dry filter tends to be unstable [228].

Operation. In the operation of rapid filters, it is frequently preferred to keep the filtration rate constant during a run. This requires suitable control because the resistance to flow in the filter bed increases with increased filter running time due to turbid deposits. A constant filtration rate can be achieved by throttling the filter outflow at the beginning of the run. Throttling is then reduced, corresponding to the increased pressure drop due to loading of the filter bed. In open filters, especially; the same result can be achieved by an appropriately increasing head of water. In some cases, operation with variable filtration rates is preferred, the rate decreasing to about half of the starting value during a filter run. Depending on the raw water properties, the average filtrate quality can be somewhat better than that obtained with a constant filtration rate in the same filter unit. This results from the fact that the lower the flow rates, the lower is the probability of turbidity deposits being detached and washed out due to the shear forces in the filter.

The running time of rapid filters is normally between 10 and 150 h. In this time, both filtrate quality (expressed as volume concentration of turbidity c) and pressure drop over the filter bed (Δp_V) change, as shown qualitatively in Figure 36. In the continuous monitoring of filtration plants, a simple turbidimetry is generally used in practice to determine the turbidity level. As shown in Figure 36 three characteristic phases of a filter run can be distinguished. The level of turbidity in the filter outflow decreases up to time t_1. This is the period of ripening, which can be very pronounced, especially when chemical – catalytic or biological processes are important for filtering action. The level of turbidity in the filtrate is approximately constant between t_1 and t_2. The breakthrough phase of the filter starts at t_2. The filter run can continue until the maximal permissible concentration of turbidity-causing particles is reached (e.g., at t_3); then the filter must be backwashed. Furthermore, Figure 36 shows that the pressure drop over the filter bed increases with filter running time and reaches its maximum permissible value at t_4. One of the important optimization tasks in rapid filtration consists of making t_3 and t_4, the two times that limit the filter run, coincide as much as possible. For safety reasons (i.e., to make sure that the turbidity in the filtrate never becomes too high), the t_3 value chosen in practice is often ca. 10 – 20 % greater than t_4, and attainment of the maximum permissible pressure drop is used as the primary criterion for terminating a filter run.

Figure 36. Change in pressure drop and in turbidity with time in the filtrate of a rapid filter at a constant filtration rate

Regeneration. At the end of its running time, a classic rapid filter must be regenerated. This is usually carried out in a backwashing process in which the upward flow through the filter layer is so strong that the turbid deposits on the filter grains are detached and discharged. In *single-medium filters*, backwashing is often carried out with water only. The flow rate must be so high that the filter bed is converted from a fixed bed to a fluidized bed. To achieve more intensive purification of the filter grains, air can be used in addition as backwash medium. In the first phase, the filter layer with a slight water head is whirled up only with air, causing a reduction of possibly hardened filter grains. Subsequently, backwashing is often conducted with air and water, followed by water alone.

Multimedia layers are treated analogously. In most cases, however, simultaneous air – water backwashing is omitted because the danger of losing filter material with the wash water is too great. In multimedia filtration, the last phase involves a reclassifying process, which causes the different filter media to separate so that the original layer setup of the filter is reproduced. In this process relatively high wash water rates are applied; expansion of the filter bed can reach ca. 40 % in the process.

A filter backwash usually requires 10 – 20 min. Depending on grain size and density, the wash air and wash water rates vary from ca. 30 to 100 m/h with a filter bed expansion of 10 – 50 %. In a well-designed filter wash program, the water consumption based on the filter area should be not greater than 2 – 5 m^3/m^2 per wash. If the removal of turbidity in the filter depends greatly on biological or chemical – catalytic processes, excessive filter backwashing can be a disadvantage because a relatively long period of filter ripening is required.

8.4.3. *Filter Performance*

To design and operate a rapid filter optimally, both the volume concentration *c* of a certain type of particle and the filter load σ, which are functions of filter layer depth *z* and filter running time *t*, should be predeterminable under given feed conditions. The load σ determines the pressure distribution *p* in the filter layer and, finally, the total pressure drop. To describe *c*, σ, and *p* as a function of *z* and *t*, a mass balance, a kinetic equation for the mass transfer from the flowing phase to the stationary filter material, and a relation to describe the pressure distribution in the filter are required for a differential filter element [228], [233], [234].

The simplified *mass balance* is as follows:

$$v_f \frac{\delta c}{\delta z} + \frac{\delta \sigma}{\delta t} = 0$$

where v_f is the filtration rate; *c* the volume concentration of particles; σ the filter load (volume of particles removed, based on filter layer volume); *z* a space coordinate (filter layer depth); and *t* the filter running time.

For the *kinetic equation*, the relation proposed by IWASAKI [235] is generally used. It corresponds formally to first-order reaction kinetics:

$$\frac{\delta c}{\delta z} = -\lambda \cdot c$$

The filtration coefficient λ is a measure of filter efficiency. It corresponds to the probability of a certain particle being retained in the filter layer. The filtration coefficient depends on the properties of the filter material (e.g., grain size) and of the particles (e.g., particle size, density, and surface charge) and on filter operating conditions (e.g., filtration rate). However, λ also changes with increasing filter running time because of the increase in filter load with time. For this reason, λ is usually formulated as follows [236]:

$$\lambda = \lambda_0 \cdot f_\lambda$$

λ_0 represents the filtration coefficient in the initial phase of filtration (i.e., as long as the influence of the filter load is still negligible); f_λ is a correction function, which essentially describes the effect of the filter load on particle deposition. In the idealized model case, f_λ decreases linearly with filter load, i.e., $f_\lambda = 1 - \sigma / \sigma_s$ (σ_s: saturation or maximum load). Then, the following analytical solution for the distribution of the particle concentration in the filter layer can be obtained from the two partial differential equations for the mass balance and for the kinetic equation

$$\frac{c}{c_0} = \frac{\exp\{\lambda_0 \cdot v_f \cdot c_0 \cdot t/\sigma_s\}}{\exp\{\lambda_0 \cdot z\} + \exp\{\lambda_0 \cdot v_f \cdot c_0 \cdot t/\sigma_S\} - 1}$$

where c_0 is the volume concentration of particles in the filter inflow. In case of a more complicated dependence $f_\lambda = f(\sigma)$, numerical solutions for describing the distribution of the concentration and load must be applied. The same holds true in describing the pressure distribution in the filter layer, which is usually based on the Carman – Kozeny equation [228], [233], [234] (⟶ Filtration – Filtration Models).

For the initial phase of filtration ($t \longrightarrow 0$), the above equation results in an exponential decrease in the volume concentration

of particulates with bed depth, according to the following:

$$\frac{c}{c_0} = e^{-\lambda_0 \cdot z}$$

where λ_0 is determined by various forces that act within the filter layer on a particle to be deposited. These forces must not only bring a particle into contact with the surface of the filter material (transport mechanisms), but also make possible sufficiently stable particle adhesion (adhesion mechanisms) on contact. Particle separation is thus influenced by many parameters, including the filtration rate and the size, shape, and surface charge of the filter material. The properties of water such as density and viscosity, the pH value, and the other dissolved water constituents are also important. In addition, the properties of the turbidity-causing solids, such as density, particle size and shape, surface charge, and shear strength, sometimes play a dominant role. The important classic separation mechanisms in deep-bed filtration of liquids are shown in Figure 37. In the case of *interception* (Fig. 37 A), a particle is assumed to move through the filter layer with its center along a stream line. It can come in contact with the surface of a grain as a result of the constriction of stream lines due to neighboring filter grains. In the case of *sedimentation* (Fig. 37 B), the particle can leave its original stream line and come in contact with the filter material under the effect of gravity. If the turbidity-causing particle has a size <1 µm, a particle – grain contact can also occur due to *particle diffusion* (Fig. 37 C).

Figure 37. Schematic representation of classic particle deposition mechanisms in deep-bed filtration of liquids

A) Interception; B) Sedimentation; C) Particle diffusion*d* = diameter of filter grain; *x* = diameter of turbidity-causing particle

Despite the extremely diverse influencing factors, the success of particle deposition in rapid filters usually increases with larger particle size, higher particle density, lower filtration rate, and smaller filter grain size. However, a decreasing filter grain size results in an increasing pressure drop. In addition, excessively high electrostatic respulsion forces as a result of surface charges of the same sign on turbidity-causing particles and filter materials must not occur. These repulsion forces can prevent particle deposition. In this respect, appropriate water pretreatment can be of considerable significance.

Under normal conditions of water treatment, a range of ca. 1 – 10 m^{-1} can be given as a rough guide for λ_0. The maximum load σ_s attainable is usually < 2 % [228], [236].

9. Membrane Separation Processes in Water Treatment

Robert Rautenbach

(see also, ⟶ Membranes and Membrane Separation Processes)

Since the 1980s, membrane processes have been used increasingly in separation technology. The main emphasis was put on the treatment of aqueous solutions. In many cases, such as the desalination of brackish water, membrane processes have set the standard against which all other alternatives must be compared with regard to operating and investment costs.

In general, membrane processes are characterized by the following properties:

1. They can operate at ambient temperature.
2. They separate on a purely physical basis so that the components are not altered and can, in principle, be reused.
3. They have a modular setup so that they can be adapted to any separation capacity relatively easily and later expansion is possible (in contrast to biological processes).

With regard to the production and treatment of drinking water and wastewater treatment, the microfiltration – ultrafiltration and nanofiltration – reverse osmosis are of special significance (⟶ Membranes and Membrane Separation Processes – Ultrafiltration, Microfiltration, and Reverse Osmosis). This chapter is restricted to these processes.

In these processes, the component that passes preferentially through the membrane is the solvent (i.e., water in the case of aqueous solutions). In all the aforementioned processes, the driving force for this transport results from a transmembrane pressure difference. However, the magnitude of pressure difference and, especially, the type of membrane used differ in these processes. Whereas pore membranes are used in microfiltration and ultrafiltration (UF), nonporous solution-diffusion membranes are employed in nanofiltration (NF) and reverse osmosis (RO).

9.1. Principles

9.1.1. *Flow, Selectivity, Driving Forces*

Microfiltration and Ultrafiltration. In pore membranes, *selectivity* results basically from the pore-size distribution of the membrane. Characterization of the membrane is carried out by permeation experiments with aqueous solutions of macromolecular substances of varying molar masses (Fig. 38).

Figure 38. Separation characteristics of ultrafiltration membranes

PEG = Poly(ethylene glycol)

Like the flow through a particle bed, the *flow of solvent* through pore membranes (i.e., the performance of the membrane) is a viscous flow proportional to the transmembrane pressure difference.

$$\dot{m}_w'' = A\varrho_w \Delta p \tag{9.1}$$

where $\dot{m}''$ is the mass flow rate per unit area (flux), ϱ_w is the density of water, and Δp is the pressure difference across the membrane. The constant A is membrane and substance specific (influence of solvent viscosity) and is determined experimentally. In most applications of micro- and ultrafiltration, a *surface layer* forms on the membrane that consists of retained components. This formation can rarely be prevented and is often even desirable. This layer is more important than the real membrane with regard to the separation characteristic and performance (permeate flux). Therefore, in the case of micro- and ultrafiltration, experiments under operating conditions are mandatory — processes cannot be designed based on performance data of the membrane alone.

Since the thickness and structure of the surface layer are influenced by conditions of flow of the feed solution along the membrane, the hydrodynamics in the membrane module is of great importance. In many cases (e.g., the separation of protein from whey), the permeate flux can in practice be influenced only by hydrodynamics and is independent of the transmembrane pressure difference (Fig. 39, see also Section Mass Transport Resistance in Front of the Membrane).

Figure 39. Influences on the performance of ultrafiltration

A) Influence of pressure difference (operating conditions: w_p = 0.8 %, ϑ = 25 °C, n = 500 min^{-1}; membranes: △ = UF-00 Kalle; ○ = UF-0 Kalle; □ = CA-19000 Kalle); B) Influence of flow conditions (operating conditions: ϑ = 25 °C, Δp = 4 bar

a) n = 550 min^{-1}; b) n = 300 min^{-1})

n = impeller speed

The measured values shown in Figure 39 are steady-state values, i.e., values obtained after a certain operating time, corresponding to Figure 40, curve a.

Figure 40. Behavior with time of surface layer-controlled flux

a) Reversible formation of surface layer; b) Irreversible formation of surface layer

When a reversible surface layer is formed, an equilibrium exists between deposition of the retained components on the upper side of the surface layer as a result of permeate flux through the membrane and removal of surface layer components due to shear stresses caused by tangential flow. The use of ultrafiltration instead of sedimentation for the separation of biomass after a biological treatment stage represents an example of this behavior. In this case, a constant permeate flux of ca. 100 L m^{-2} h^{-1} has been observed over several weeks with tubular modules at tube flow rates of ca. 4 m/s [237]. Formation of a reversible surface layer is often encountered in ultrafiltration (and microfiltration), but the behavior with time shown in curve b (formation of an irreversible surface layer) is encountered just as often. When an irreversible surface layer is formed, the operating time after which the unit should be cleaned is then determined by the economics of the process.

Reverse Osmosis. In nonporous membranes for reverse osmosis and nanofiltration, transport generally is determined by the mass transport resistance of the membrane and not by a surface layer. However, modeling mass transport in the membrane is more difficult than in ultrafiltration, especially in the case of organic – aqueous solvent mixtures and, in nanofiltration, in the case of a multicomponent salt solution with monovalent and multivalent anions.

If the membrane is regarded as a continuum in which the permeating components are first sorbed, then transported by diffusion, and finally desorbed, equations can be derived for any permeating component "i ", e.g., i = W (water), i = S (salt or dissolved organic substance) by the integration of the generalized Fick law over the membrane thickness.

$$\dot{n}_i'' = -c_i \frac{D_{io}}{RT} \frac{d\mu_i}{dz} \tag{9.2}$$

where $\dot{n}$ is the molar flux, D_{io} the thermodynamic diffusion coefficient, μ the chemical potential, and z the thickness of the membrane. Depending on the degree of simplifying assumptions, these equations vary with regard to complexity and

descriptive accuracy. Table 30 shows three such equation systems for reverse osmosis, as well as cases in which they describe flux and selectivity with sufficient accuracy.

Table 30. Models for describing mass transport in reverse osmosis membranes

Model	Transport relation	Application
1	$\dot{m}_p'' \approx \dot{m}_w'' = A\varrho_w(\Delta p - \Delta\pi_w)$	production of ultrapure water
	$R \equiv \frac{w_{S_F} - w_{S_P}}{w_{S_F}}$	from drinking water
2	$\dot{m}_w'' = A_{\varrho w}(\Delta p - \Delta\pi_w)$	production of drinking water
	$\dot{m}_S'' = B\left(w_{S_F} - w_{S_P}\right)$	from brackish water
3	$\dot{m}_w'' = A^* \frac{1}{1+kw_{S_F}}\left(\Delta p - \Delta\pi_w\right)$	concentration of aqueous – organic solutions
	$\dot{m}_w'' = B^* \frac{kw_{S_F}}{1+kw_{S_F}}\left(\Delta p - \Delta\pi_S\right)$	wastewater treatment

The following assumptions are common to all three relations:

1. Equilibrium of the chemical potentials μ_i at the phase boundaries on both sides of the membrane: i.e., $\mu_i^F = \mu_i^{FM}$, $\mu_i^P = \mu_i^{PM}$ (where the index F denotes feed, M denotes membrane, P permeate, FM feedside of the membrane, and PM permeate side of the membrane).
2. No coupling of the permeate flows of different components: i.e., only the gradient of the chemical potential of the component μ_i is regarded as the driving force for transport of component *i* of a mixture through the membrane

The question which equation can or must be used to describe local mass transport (i.e., the mass transport at a certain point of the membrane) for a certain application can only be solved experimentally. For instance, in the reverse osmosis of dilute sodium chloride solutions, a constant rejection *R* can be assumed — i.e., a constant ratio of the (local) salt concentration in the permeate to the local feedside concentration. In contrast, this ratio (or the rejection) is highly concentration dependent in the case of an aqueous butanol solution.

The problem can be explained by the example shown in Figure 41. In the case of a phenol – water mixture, significant differences between experiments and calculations are observed even at very low phenol concentrations when the calculation is based on model 2. The three-parameter model 3 must be used here.

Figure 41. Decrease in flux in reverse osmosis caused by traces of organic compounds (phenol) [238] (operating conditions: phenol – water mixture, Δp = 30 bar; Θ = 25 °C)

a) Measurements performed with membrane SU 700; b) Measurements performed with membrane FT 30

——— = calculated according to model 2; – – – = measured

Nanofiltration. In principle, nanofiltration membranes are nonporous solution – diffusion membranes like reverse osmosis membranes [239]. However, they have a low rejection for low molar mass substances. Nanofiltration is characterized by two extremely interesting properties:

1. The ability to fractionate organic components of varying molar mass and/or structure in aqueous solutions (e.g., mixtures of mono- and polyhydric alcohols)
2. The possibility of utilizing the Donnan effect (⟶ Membranes and Membrane Separation Processes; ⟶ Ion Exchangers – Principles) whereby through the addition of one ionic species (e.g., SO_4^{2-} ions), the rejection capacity for another ionic species (e.g., NO_3^-) is drastically decreased.

This selectivity of nanofiltration for organic components in the molar mass range 100 g/mol < *M* < 300 g/mol is shown in Figure 42. For example, the rejection capacity of the membrane “Desal 5” is only ca. 30 % for ethylene glycol, but more than 80 % for glucose. These results were obtained from experiments with binary solutions of the same osmolarity (i.e., the same driving force) [238].

Figure 42. Separation characteristics of nanofiltration in organic aqueous systems (operating conditions: Δp = 10 bar; Θ = 25 °C; osmotic concentration x_F = 200 mOsmol per kilogram H_2O)

1 = Methanol; 2 = Ethanol; 3 = *n*-Butanol; 4 = Ethylene glycol; 5 = Triethylene glycol; 6 = Glucose; 7 = Sucrose; 8 = Lactose

The Donnan effect is illustrated in Figure 43. The addition of SO_4^{2-} ions, in the form of Na_2SO_4, reduces the rejection capacity for Cl^- ions significantly, even to negative values, while the rejection capacity for Na^+ ions increases slightly.

Figure 43. Influence of the addition of SO_4^{2-} in the form of Na_2SO_4 on Cl^- rejection (operating conditions: membrane XP 45; *c* NaCl = 0.05 mol/L) [239]

a) Na^+ rejection; b) Cl^- rejection

9.1.2. *Mass Transport Resistance in Front of the Membrane*

In reverse osmosis and nanofiltration, where mass transport is membrane controlled in normal operation, the separation performance is usually overestimated if only the resistance of the membrane is considered. A concentration boundary layer on the side of the raw mixture (in front of the membrane) can, in unfavorable cases, clearly reduce the performance of the membrane and the quality of separation. The steady-state local conditions are shown qualitatively in Figure 44. For the purpose of this discussion, a binary solution is used.

Figure 44. Concentration polarization on the feed side of a reverse osmosis or nanofiltration membrane

$\dot{m}''_{S,\,diff}$ = mass flux of salt per unit area by diffusion; $\dot{m}''_{S,\,conv}$ = mass flux of salt per unit area by convection; $\dot{m}''_{W,\,diff}$ = mass flux of water per unit area by diffusion; $\dot{m}''_{W,\,conv}$ = mass flux of water per unit area by convection; δ_F = thickness of the concentration layer

The concentration profiles indicated schematically in Figure 44 are formed in front of the membrane due to the selectivity of the membrane. The concentration *w* of the preferentially permeating component W (water) decreases toward the membrane, and the concentration of the preferentially rejected component S, corresponding to $w_S = 1 - w_W$, increases. This phenomenon is called *concentration polarization* (⟶ Membranes and Membrane Separation Processes – Concentration Polarization in Filtration Processes). On condition that concentration gradients in the direction of flow are negligibly small compared with the orthogonal gradients, the concentration profile is described by

$$\frac{w_{S2} - w_{SP}}{w_{S1} - w_{SP}} = e^{\frac{\dot{m}''_P}{\rho_P \cdot k}} \tag{9.3}$$

with $k \equiv D/\delta$ as mass-transfer coefficient for negligible wall flux ($m''_P \longrightarrow 0$) and with

$$w_{SP} = \frac{\dot{m}''_S}{\dot{m}''_S + \dot{m}''_W} \approx \frac{\dot{m}''_S}{\dot{m}''_W} \tag{9.4}$$

the subscripts S1 and S2 denote the salt at point 1 and point 2, w_{SP} is the salt concentration of the locally produced permeate. The mass-transfer coefficient can be calculated with sufficient accuracy by means of equations valid for heat transfer, using the Sherwood number instead of the Nusselt number and the Schmidt number instead of the Prandtl number. The correlations valid for tubes and rectangular channels are listed below.

Characteristic numbers

Reynolds number = $Re = d_h\, v/\nu$

Schmidt number = $Sc = \nu/D_{ij}$

Sherwood number = $Sh = k\, d_h/D_{ij}$

where

d_h = hydraulic diameter

d_h = d (tube with diameter d)

d_h = $2\,h$ (channel with height h and width b, $b \gg h$)

v = flow rate

ν = kinematic viscosity

Laminar flow fully developed hydrodynamic but developing concentration boundary layer (Sieder and Tate [240])

$$Sh = 1.62(Re\,Sc\,d_h/L)^{1/3}\; 30 < Re\,Sc\,d_h/L < 10^4$$

Turbulent flow (Linton and Sherwood [241])

$$Sh = 0.04\,Re^{3/4}Sc^{1/3}\; 10^4 < Re$$

The degree of concentration polarization is definitely determined by the hydrodynamics in front of the membrane. Good

hydrodynamics is of great importance for the development of modules (technical membrane configuration).

Estimation of the effect of concentration polarization in a technical membrane module is shown in Figure 45. The ratio of real flux to maximal possible flux (pure membrane resistance) is plotted against the ratio of the mass-transfer coefficient k to the pure water flux $A \cdot \Delta p$ (see Fig. 45). Clearly, the more efficient the membrane, the more important are proper hydrodynamics. (In order to control concentration polarization, k must increase with increasing values of $A \cdot \Delta p$).

Figure 45. Influence of mass-transfer coefficient on the local performance of a membrane module [operating conditions: system water – NaCl – FT 30 SW; $A = 4\times10^{-7}$ m s^{-1} bar^{-1}; $B = 9.33\times10^{-5}$ kg m^{-2} s^{-1}; b = 8 bar per wt % NaCl; ρ_F = 1000 kg/m^3; w_S^* = 0.035 %; p_F = 60 bar; p_p = 1 bar; R = 1; $\dot{m}''_p = A\,\rho_i\,(\Delta p - b\,w_S)$; $\frac{w_{S,2}}{W_{S,1}} = \exp\left(\frac{\dot{m}''_P}{\rho_i k}\right)$

$m''_p\,(w_{S2})/m''_p\,(w_{S1})$ = permeate flux with concentration polarization/permeate flux without concentration polarization

a) $bw_{S1}/\Delta p$ = 0.1; $bw_{S1}/\Delta p$ = 0.3; c) $bw_{S1}/\Delta p$ = 0.5; d) $bw_{S1}/\delta p$ = 0.8

A special case of Equation (09.3) describes ultrafiltration in the surface layer-controlled region. In this region the stationary final value of the transmembrane flow (see Fig. 40, curve a) becomes fully independent of the transmembrane pressure difference (Fig. 39 A).

If the concentration in the boundary layer reaches saturation concentration, the system compensates for any further increase in driving force by an increase in surface layer. For a binary system consisting of water and dissolved macromolecules (e.g., proteins), which are quantitatively retained by the UF membrane, Equation (9.3) becomes

$$\frac{w_{P,max}}{w_{P,1}} = e^{\frac{\dot{m}''_P}{\rho_P k}} = \text{const.} \qquad (9.5)$$

In this case, the permeate flux is determined only by the saturation concentration $w_{P,max}$, the concentration of the feed, and the hydrodynamics.

9.2. Membranes

(⟶ Membranes and Membrane Separation Processes – Membrane Preparation and Membrane Module Constructions)

For the projecting and process development of any membrane separation process, a large range of selective and stable membrane materials is available. These materials have been optimized for many different applications. Because of the great variety of materials, the nature and efficiency of membranes must be described separately for each process.

Nevertheless, to better understand the processes occurring in a membrane, a short general introduction to the materials and structures of commercially available membranes is given. This discussion is limited to synthetic solid membranes, which are made of both organic and inorganic materials.

9.2.1. *Organic Membranes*

In organic membranes [242-244], the choice of membrane-forming polymer for a concrete separation problem is not arbitrary but is oriented to the following properties of the polymer:

1. Molar mass
2. Chemical structure and spatial arrangement of the macromolecules
3. Interactions between different macromolecules

The structural properties determine both the macroscopic properties of the membrane, such as thermal, chemical, and mechanical stability, and the microscopic “inner” properties, such as the permeability of the polymer to a certain component.

The demand for the highest possible permeate flow requires that the actual selective layer of a membrane be as thin as possible because the flow of a component is inversely proportional to membrane thickness.

As a consequence, membranes usually have an *asymmetric structure*. They consist of a very thin skin (active layer) and a porous support layer. As the actual selective barrier for mass transport, the active layer essentially determines the separation efficiency of the membrane.

In the case of asymmetric polymer membranes, integral-asymmetric and composite-asymmetric structures can be distinguished. *Integral-asymmetric membranes* are made by phase inversion (i.e., precipitation of the polymer from a homogeneous solution). The active layer and the substructure consist of the same material. The most successful materials used for integral-asymmetric reverse osmosis membranes are, e.g., cellulose acetate and polyamide.

In the case of *composite-asymmetric membranes*, a homogeneous polymer layer, which is as thin as possible, is applied to a microporous or porous structure. These membranes, called composite membranes, allow individual optimization of the selective layer and the porous support layer with regard to separation efficiency and mechanical, thermal, and chemical stability. In reverse osmosis, the support layer of many membranes is made of polysulfone, and the selective layer is made of, e.g., polyethyleneimine.

9.2.2. *Inorganic Membranes*

Apart from organic membrane materials, inorganic membranes have become increasingly important since the 1980s [245]. Their advantages are:

1. High temperature stability
2. Chemical stability
3. No aging; long service lives
4. Backwashing possible
5. Controllable separation limit and separation efficiency

Their disadvantages are

1. Sensitivity to tension and bending
2. High investment costs
3. Use of temperature-sensitive sealing materials, which limits full utilization of the temperature stability of the membranes

Inorganic membranes are not nearly as important as organic membranes. Materials used are carbon and zirconium oxide – aluminum oxide.

9.3. Modules

(⟶ Membranes and Membrane Separation Processes – Membrane Preparation and Membrane Module Constructions)

As mentioned above, membrane systems are modular (i.e., made up of individual modules). In module development, the following requirements, which are partly contradictory, are essential:

1. Good hydrodynamics (e.g., no dead zones)
2. Mechanical, chemical, and thermal stability of the module
3. High packing density of the module
4. Inexpensive production
5. Good cleaning possibilities
6. Inexpensive replacement of a membrane
7. Low friction losses

Module design must be oriented to these requirements. Since the main emphasis is on one or another requirement, depending on application, many completely differently designed module types are available on the market. Disregarding design details, the modules can be divided into two classes and six types:

Tubular Membranes	Flat-sheet Membranes
Tubular module	Plate and frame module
Capillary module	Spiral-wound module
Hollow-fiber module	Disk module

9.3.1. *Modules with Tubular Membranes*

Tubular Module. In this type of module, the membrane lies in the form of a tube on the inner side of pressure-stable pipes having a diameter of 6 – 24 mm. The mixture to be separated is pumped through the inside of the tube; the permeate is collected outside. If the supporting pipe is made of a material that is impermeable to the filtrate, a thin porous tubular fleece (e.g., of porous polyethylene) is placed between the supporting pipe and the membrane. This fleece does not impede the transport of the filtrate to the bores arranged at short intervals in the supporting pipe and provides the necessary support for the membrane, especially in the region of these bores. Membranes are partly replaceable and partly attached firmly to the supporting material. To increase the relatively low packing density (<80 m^2 of membrane area per cubic meter of space enclosed), many producers arrange several modules in one jacket pipe (Fig. 46).

Figure 46. Tubular modules in jacket pipe

Capillary Module. Unlike tubular modules and modules with flat-sheet membranes, in which the membrane film is mechanically supported by a porous supporting structure, capillary and hollow-fiber membranes are pressure-stable.

The capillary module consists of larger (d_i = 0.5 – 6 mm) membrane capillaries, which have an asymmetric structure with the selective layer on the inside. The capillary module can be compared with a shell-and-tube heat exchanger. The membrane capillaries are arranged in parallel bundles potted in epoxy resin, thus forming a head plate at both ends. Capillary modules have a higher packing density than tubular modules. However, mass transfer conditions are inferior because of laminar flow (see Section Mass Transport Resistance in Front of the Membrane).

Hollow-Fiber Module. Hollow-fiber modules have much smaller diameters (outer diameters 85 – 200 µm) than capillary modules. Hollow-fiber modules are employed in reverse osmosis.

In reverse osmosis, the mixture to be separated is always on the outside of the fiber (i.e., the selective layer is also on the outside), while the permeate flows in the lumen. In contrast to capillaries, hollow fibers are exposed to external pressure. These are favorable conditions, and accordingly hollow-fiber modules can resist pressure differences up to 100 bar. The individual fibers of a hollow-fiber module are assembled to a bundle and installed in a pressure vessel.

9.3.2. *Modules with a Flat-Sheet Membrane*

Plate and Frame Modules. Plate and frame modules are used in reverse osmosis, microfiltration, and ultrafiltration. All designs have the following essential elements: the flat membrane; the support plate for the membrane; and plates for guiding the flow on the feed side. The elements are assembled in form of stacks.

An advantage of plate modules is that the permeate from each membrane pair is collected separately. Thus, membrane defects can be recognized and repaired by disconnecting the defect membrane pair without shutting down the entire module. In all plate modules, a disadvantage is the high number of individual seals and the relatively high friction losses caused by 180° changes in flow direction.

Spiral-Wound Modules. The spiral-wound module is the most widely used module type. It was first developed for reverse osmosis and is also used in nanofiltration and ultrafiltration. The design of a spiral-wound module is shown in Figure 47. In this module, one or several membrane pockets, each with a netlike spacer made of plastic, are wound spirally around the permeate-collecting tube. The membrane pocket consist of two membranes with a porous plastic fleece between them (permeate spacer). The membrane pocket is sealed on three sides and is connected to the perforated permeate-collecting tube on the fourth open side. Feed solution enters at the front surface and flows in axial direction through the module, while the permeate flows spirally within the porous support layer toward the collecting tube.

Figure 47. Schematic of a spiral-wound module

a) Membrane; b) Permeate-release layer; c) Spacer; d) Cover

Spiral-wound modules have gained acceptance to a great extent because they combine a simple and inexpensive design with relative insensitivity to fouling and a relatively high packing density (up to 1000 m^2/m^3).

Disk Module. The concept of the disk module is comparable with that of the spiral-wound module. Here, too, two individual membranes are combined with a fabric fleece between them. However, the entire periphery of the disk is sealed. The permeate is collected centrally through an opening provided with an O-ring. A clamping bolt is also located in the central hole. It compresses the membrane disks and spacers in such a way that the permeate flow is sealed off from the raw mixture. The advantages of the disk module are, above all, the low pressure drops on the permeate side and a low susceptibility to plugging on the feed side (this is due to the more “open” spacers of the disk module, compared to the feedspacer of the spiral-wound module). The disadvantage is a relatively low packing density (<400 m^2/m^3) (Fig. 48).

Figure 48. Disk module

Disk modules are used today up to pressure differences of Δp = 200 bar. This is of interest when, in the solutions to be treated, the osmotic pressure determines the limit of concentration. Spiral-wound modules are operated today at maximum pressure differences of 120 bar.

9.4. Fouling and Scaling

(⟶ Membranes and Membrane Separation Processes – Concentration Polarization and Membrane Fouling)

The efficiency of reverse osmosis and nanofiltration is often limited not by the osmotic pressure or the viscosity of the feed solution, but by two other phenomena:

1. *Scaling*: Membrane blockage due to increase in concentration of the dissolved constituents in the feed until the solubility limit is exceeded and the constituents precipitate on the membrane surface
2. *Fouling*: Membrane blockage because of suspended or colloidally dissolved substances carried in or because of growth of microorganisms

9.4.1. *Membrane Blockage due to Crystallization (Scaling)*

If the solubility limits of certain substances are exceeded in an aqueous system during the concentration of constituents, the substance precipitates and can form a layer on the membrane surface. In many cases, these layers can be removed from the

membrane by washing with acid (e.g., citric acid). Especially in the case of spiral-wound and hollow-fiber modules, however, flushing the crystal sludge out of the module is difficult or impossible. For this reason, scaling must be avoided by, e.g.,

1. Chemical conversion, elimination, or stabilization of the substances
2. Restriction of concentration increase in such a way that the saturation concentration of none of the dissolved components is reached even at the critical spot of highest concentration (i.e., the membrane surface at unit exit)

To estimate this concentration limit or to estimate the required raw water pretreatment, the following properties in water analysis must be taken into account:

1. Temperature, pH, conductivity, total dissolved solids (TDS)
2. Acid – base capacity (*m* alkalinity, *p* alkalinity)
3. Concentration of Na^+, Ca^{2+}, Ba^{2+}, Sr^{2+}, Mn^{2+}, Fe^{2+}
4. Concentration of Cl^-, SO_4^{2-}, NO_3^-, F^-, HCO_3^-, CO_3^{2-} (from *m* and *p* alkalinities)
5. Concentration of SiO_2, free Cl_2, O_2, and CO_2 (from *m* and *p* alkalinities)

For the most important dissolved solids, calculations of the solubility limit or maximum possible concentration in the module are available in the literature [246-252].

Important water pretreatment measures (e.g., against $CaCO_3$-scaling) are acid dosing $(HCO_3^- \rightarrow CO_2\uparrow)$; precipitation; and softening (substitution of Na^+ for Ca^{2+}).

Measures against $CaSO_4$ scaling are limiting or even lowering of the water recovery rate so that $CaSO_4$ precipitation is avoided in all events; softening (substitution of Na^+ for Ca^{2+}); precipitation ($Ca^{2+} \longrightarrow CaCO_3 \downarrow$); and stabilization by polyphosphate or organic antiscalants.

9.4.2. *Membrane Blockage due to Contaminants (Fouling)*

In practice, the formation of a surface layer due to suspended or colloidally dissolved substances carried in (and often not eliminated despite very careful pretreatment) or to the growth of microorganisms is the weak point of reverse osmosis. Although the thickness of the surface layer formed during operation is barely measurable, it represents a considerable additional resistance for the permeating components. Therefore, for safe operation of reverse osmosis plants, the fouling behavior must be studied in practice-related experiments with the real system “prefiltered raw water – original membrane.” Pretreatment measures for the prevention of fouling in reverse osmosis are [253-257] (⟶ Flocculants)

1. Filtration through a sand or multimedia deep bed, usually in combination with flocculation
2. Polishing filtration using cartridge filters
3. Microfiltration or ultrafiltration
4. Flotation

9.5. Module Arrangements (Plant Design)

Especially in reverse osmosis, nanofiltration, and ultrafiltration, proper hydrodynamics on the feed side are of central importance. In a continuously operating plant, the mass flow rate (decreasing) and the concentration (increasing) on the feed side change because essentially pure water is transferred from the feed to the permeate at every point of the membrane. In this connection, two module arrangements that take this problem into account are especially important (Figs. 49 and 50): (1) the tapered design and (2) the feed and bleed design, a plant structure made of several module blocks with circulation pumps.

Figure 49. Flow diagram of tapered design

Figure 50. Flow diagram of feed and bleed design (module blocks with circulation pumps)

The *tapered design* is normally used in very large plants for desalination of sea- and brackish water. Plants with *feed and bleed design* are used especially in wastewater treatment where smaller mass flow rates with a greater contamination potential must be treated.

9.6. Use of Membrane Processes in Water and Wastewater Technology

9.6.1. *Desalination of Seawater and Brackish Water*

Fresh water can be separated from sea- or brackish water by (1) evaporation, if the phase transition of water during the separation process is accepted, and (2) membrane processes, where no phase transition occurs [258]. At present and in the near future, seawater will be desalinated mainly by evaporation processes. However, reverse osmosis is an attractive alternative to thermal processes.

The membranes used in the desalination of seawater and brackish water are either composite membranes (e.g., Dow-

Filmtec's FT 30, the membrane Desal 3 of Desalination Industries) or asymmetric phase inversion membranes made of polyamide (e.g., by DuPont). The modules used are spiral-wound, hollow-fiber, and disk modules.

In all RO desalination plants in operation, the great effort involved in the pretreatment of water is conspicuous. The extent of treatment depends, first, on the composition of the raw water and, second, on the module concept employed. The required pretreatment is directly proportional to the sensitivity to fouling and scaling of the module type employed. In disk modules with a relatively open feed channel, adjustment of the pH, chlorination, and separation of the suspended solids by sand filtration are sufficient. In spiral-wound or hollow-fiber modules, additional fine filtration by cartridge filters is required. In general, treatment includes the following steps:

1. Chlorination to prevent growth of algae
2. Filtration (e.g., by a combination “sand filter and subsequent precoat filter”)
3. Adjustment of pH
4. Addition of hexametaphosphate to prevent $CaSO_4$ precipitation in the modules
5. Fine filtration with a 10-µm cartridge filter (5-µm cartridge filter in the case of hollow-fiber modules)

Based on a large-scale operating plant, main design features of a reverse osmosis plant for the desalination of seawater are discussed below.

Seawater Desalination Plant in Las Palmas, Gran Canaria. This seawater desalination plant was put into operation in 1989 (Fig. 51). It has a capacity of about 36 000 m^3/d and consists of six parallel trains of identical design. Each train consists of 128 pressure vessels, which contain six spiral-wound modules each. These are arranged in such a way that eight pressure vessels form one unit. This unit is divided into five pressure pipes in the first block and three pressure pipes in the second block (tapered design).

Figure 51. Seawater desalination plant in Las Palmas, Gran Canaria

The entire plant achieves a water yield of 45 %. The product has a concentration of dissolved substances of 450 – 500 mg/L (seawater: 38 300 mg/L). The specific energy consumption of the plant is 6.16 kW · h/m^3. A turbine at the brine discharge side of the reverse osmosis plant recovers 1.65 kW · h/m^3. The total costs of the plant including pretreatment amounted to ca. \$ 47×10^6 in 1989.

Apart from large-scale plants of this type, reverse osmosis is used especially in desalination plants with lower capacities. Reverse osmosis plants with disk modules have, for instance, fully replaced the evaporators previously used on passenger ships (cruise ships) and warships for the following reasons: (1) savings in floor space, and, even more important, in height, and (2) independence on heat sources such as ship's diesel engines.

9.6.2. *Recovery of ∈-Caprolactam*

∈-Caprolactam, $C_6H_{11}ON$, M = 113.69 g/mol, is the monomer used for the production of polyamide 6. In the production of polyamide 6, a wastewater stream containing 5 wt % of ∈-caprolactam must be treated. Besides the treatment of the water, the objective is to recover the ∈-caprolactam as a concentrated solution. This cannot be achieved with reverse osmosis because osmotic pressure limits the water recovery rate. Assuming 45 bar as the maximum acceptable osmotic pressure of the concentrate ($\Delta\pi < \Delta p$), the concentration of the concentrate is limited to 20 wt % and correspondingly, the water recovery to 75 %. In the example considered here, 254 m^3 of ∈-caprolactam solution accumulates per day so that after the membrane unit a concentrate flow rate of 63.5 m^3/d is obtained which would have to be further concentrated (e.g., by evaporation). In addition, elaborate pretreatment would be required because wastewater has a high fouling potential. Thus, evaporation is carried out before reverse osmosis. Figure 52 shows the flow diagram of the process. The recovered ∈-caprolactam can be reused for the production of polyamide 6. The condensate, which still contains ca. 0.1 % of ∈-caprolactam is concentrated to 5 % in a reverse osmosis stage and recycled to the evaporation stage. The reverse osmosis permeate can be used in the producton.

Figure 52. Flow diagram of a plant for separation of ∈-caprolactam from evaporator condensate

The membrane plant in use is equipped with 15 pressure vessels, which contain four 8-inch spiral-wound modules each. The water recovery is 98.4 %, and the rejection of ∈-caprolactam is >99 %.

9.6.3. *Leachates from Dump Sites*

According to the latest version of the German water management law (Wasserhaushaltsgesetz) [259] and successive decrees, leachates from dump sites must be treated before discharge.

Since garbage, industrial solid waste, and special waste have different constituents, the composition of leachates from dump sites depends not only on the age, mode of operation, and construction of the disposal site, but especially on the disposed substances. The average composition of leachates from garbage disposal sites (operating in the stable methane phase) is given in Figure 53.

Figure 53. Average composition of dumpsite leachate

In last ten years, the following process variants have proved especially favorable for the treatment of leachates from dump sites:

1. Combination of biological treatment and adsorption
2. Combination of biological treatment and nanofiltration with recirculation of the concentrate from nanofiltration into the bioreactor, partial removal of organics from the NF concentrate by adsorption or ozonation, if necessary.
3. Combination of membrane processes, e.g., RO – high pressure RO – drying of the concentrate – nitrogen removal

Biological Processes. In treating leachates from disposal sites, membrane bioreactors are increasingly replacing traditional techniques (i.e., open-tank bioreactors combined with sedimentation). Instead of sedimentation, ultrafiltration in combination with an aerobic – anoxic biological treatment stage (Fig. 54) has the following advantages [260]: (1) 100 % retention of biomass, especially of the nitrifying bacteria that are problematic in sedimentation; (2) operation at significantly increased biomass concentrations (solids up to 20 – 30 mg/L), resulting in significantly increased volume-specific capacities (space – time yield).

Figure 54. Flow diagram of “BioMembrat Plus” process

With 1-inch tubular modules and feed flow rates of ca. 4 m/s, a constant permeate flux is obtained over a period of weeks (ca. 100 L m^{-2} h^{-1}). An ultrafiltration unit with a membrane area of 44 m^2 combined with anoxic – aerobic closed-vessel bioreactors (plant capacity: 50 – 65 m^3/h) is shown in Figure 55.

Figure 55. Ultrafiltration plant for separation of biomass from biologically clarified leachates

In the biological stage, easily degradable organics (BOD) and ammonium – ammonia are degraded preferentially [261]. The discharge from the bioreactor still contains

1. Recalcitrants
2. Nonbiodegradable organic compounds
3. Nonbiodegradable inorganic compounds (e.g., chlorides or heavy-metal salts)

Substances that are nonbiodegradable or poorly biodegradable are adsorbed conventionally on activated carbon. However, a combination of a membrane bioreactor with nanofiltration is an interesting alternative when the concentrate is recycled to the bioreactor, possibly after partial removal of organics from the NF concentrate by adsorption or ozonation. The mostly higher molar mass recalcitrants are rejected by NF membranes, whereas degradation products and low molar mass salts permeate the membrane with the water. If the concentrate from nanofiltration is recycled to the bioreactor, the hydraulic residence time and the residence time of the recalcitrants are decoupled, in contrast with classic biological treatment. The bioreactor then operates at much higher concentration of recalcitrants than in the raw water. As a consequence the rate of degradation increases according to the Monod law. This rate increases with increasing concentration until inhibition by toxic substances occurs.

In some cases, the amount of water discharged with excess sludge is sufficient to guarantee stable operation of the bioreactor at high concentration (prevention of inadmissible concentration of nondegradable substances in the biological treatment stage). If not, intolerable concentrations in the loop can be reduced via adsorption or ozonation. Compared to a

state-of-the-art combination “bioreactors – adsorption” or “bioreactor – ozonation”, adsorption and ozonation in combination with nanofiltration are much more efficient, because these combinations can operate at favorably high concentration levels instead of the low discharge concentration level.

Reverse Osmosis – Evaporation or Reverse Osmosis – Nanofiltration. A successful alternative to the biological treatment of dumpsite leachate is treatment by reverse osmosis in combination with further concentration steps.

In most cases the RO unit is designed as a two-stage cascade with tubular or disk modules in the first and spiral wound or disk modules in the second stage. Using a two-stage cascade with the permeate of the first stage cascade serving as feed for the second stage the legal limiting values for discharge can be safely guaranteed [262].

Reverse Osmosis – >Evaporation. Usually the RO concentrate is concentrated further by evaporation and, finally, dried when the disposal of a dry residue is stipulated. Furthermore, the process must contain a step for the separation of NH_3/NH_4^+ either a stripping unit or a bioreactor. This process combination can be considered as state of the art. Disadvantageous are the high specific energy consumption and the high specific investment costs of evaporation – dryer stages.

From the composition of leachate (Fig. 53) follows that the osmotic pressure is a limiting factor for concentration by RO. Modules are now available for operation pressures of 120 and 200 bar. By implementation of these modules into the process the evaporation stage can be eliminated. Instead of concentration factors of 2 – 3, concentration factors of up to 10 can be achieved by the RO stage.

Since only small amounts of water are removed in the drying step, which, however, gives rise to 35 – 38 % of the overall treatment costs, it must be investigated whether this process combination can be improved. A simple further increase of the water recovery rate by RO cannot be expected for two reasons:

1. Danger of calcium sulfate scaling
2. Unacceptably high membrane compaction at transmembrane pressure differences above 200 bar

As shown in Figure 53, chlorides form a major part of the inorganic components of leachates. Due to the high rejection of RO membranes for chlorides, they remain almost completely in the concentrate, resulting in a high osmotic pressure and causing disposal problem.

Reverse Osmosis – Nanofiltration. The implementation of a nanofiltration stage into the treatment process can considerably extend the limits of RO set by scaling and/or osmotic pressure. Figure 56 shows the flow diagram of the treatment process. Essentially, the concentrate of the 120 bar RO stage is treated by a combination of NF and crystallization. At moderate transmembrane pressure differences (20 – 50 bar) the nanofiltration unit produces a permeate containing mainly chlorides. This permeate can be concentrated further without danger of scaling by a 200-bar high-pressure reverse osmosis stage. Essential for the process is that the NF – crystallizer cycle is able to operate in the supersaturation range with respect to calcium sulfate and at high concentrations of organics. For this reason the success of the process depends to a large extent on a proper module design — the modules must be insensitive to fouling and to the presence of crystals. Such modules have been developed by Rochem, Germany. Stacks of rectangular membrane cushions and matching spacer plates are arranged in series in the pressure vessel in such a way that stagnant areas are avoided and internal friction losses are minimized. Feed flow is strictly parallel to the vessel axis, the velocity in the feedsite module channels is ca. 1.5 m/s.

Figure 56. Flow diagram of the combination reverse osmosis – nanofiltration – high pressue reverse osmosis for leachate treatment (Ihlenberg dumpsite, Germany)

The process has been installed and tested on a technical scale at the Ihlenberg dumpsite. A nanofiltration stage consisting of four blocks with nine modules each and a total membrane area of 180 m^2 has been added to the existing reverse osmosis – high-pressure reverse osmosis combination and comissioned in September 1994 [263]. The unit is designed for the treatment of about 4 m^3/h RO concentrate with a volumetric concentration factor of $CF_V^{RO} = 10$. Depending on the concentration factor of the 60 and 120 bar RO stage, the NF stage achieves a further concentration of $CF_V^{NF} = 10 – 20$. A sludge consisting of organics, precipitated inorganics, and water is discontinuously withdrawn from the bottom of the crystallizer – sedimentation tank.

Together with the concentrate of the subsequent 200 bar high-pressure reverse osmosis stage this concentrate is solidified with fly ash and disposed of at the dumpsite.

Cleaning of the NF modules is performed by flushing with feed at zero transmembrane pressure difference for 30 s every hour and an alkaline cleaning every 250 – 300 h. The NF rejection rate for sulfates is 92 – 95 %, for the dissolved solids 20 – 35 %.

At the Ihlenberg dumpsite the specific energy consumption of the NF and the subsequent 200 bar RO stage is 32 kW · h per cubic meter permeate. With figures of 8.5 kW · h per cubic meter of totally produced permeate and an overall water recovery rate of 97 %, the overall specific power consumption of the process is extremely low compared to other processes. With respect to residues the process can be regarded as an almost zero discharge process.

9.6.4. *Wastewater from the Dye Industry*

The production of textile dyes involves a precipitation by salting-out as the final stage. After separation of the dye, the

wastewater of the process contains the salt and, unavoidably, small amounts of dye. Treatment of this wastewater by reverse osmosis is not possible because of the high osmotic pressure and because the resulting concentrate would contain both salts and organics. However, the ability of nanofiltration to fractionate low molar mass salts and higher molar mass dyes can be used here.

A plant installed in a Swiss chemical company is shown in Figure 57. It has a total membrane area of 960 m^2 and is equipped with tubular modules because of the high fouling potential of feed. It operates at a volumetric concentration factor CF_V = 10 and has an average capacity of ca. 16 m^3/h. Since the wastewater of several dye-production plants is treated simultaneously, the NF concentrate cannot be recycled, but must be disposed of. To this end, the concentrate is subjected to wet oxidation. The permeate, containing the major part of the salts, can be discharged into the Rhine river. Here, nanofiltration has two advantages:

1. The mass flow rate of the stream subjected to wet oxidation is significantly lower.
2. The corrosion potential of this stream is strongly reduced, because the major part of the salts is removed.

Figure 57. Nanofiltration plant for treatment of wastewater from the production of textile dyes

Obviously, nanofiltration offers a possibility of recovering the dyes, at least in principle. This would be of economic interest where large amounts of only one dye are produced.

[Top of Page]

10. Oxidation Processes in Water Treatment

William H. Glaze

Oxidation processes are used in water treatment for disinfection and removal of obnoxious or potentially toxic contaminants in the water, and for some industrial purposes such as pulp bleaching and purification of wastewater before discharge into the environment. The most familiar chemical oxidant is oxygen from air; other examples of oxidants used in water treatment are chlorine, chloroamines, ozone, chlorine dioxide, hydrogen peroxide, and potassium permanganate. Sometimes these oxidants are used in combination with each other (e.g., ozone with hydrogen peroxide) or with photons from irradiation lamps. Oxidation in water treatment is often carried out with the assistance of microbiological organisms, in which case the oxidant is oxygen (⟶ Wastewater – Biological Principles, ⟶ Wastewater – Basic Biotechnological Considerations, ⟶ Wastewater). Only chemical oxidation is considered in this chapter.

10.1. Physical and Chemical Properties of Chemical Oxidants

The power of a chemical oxidant to cause a chemical oxidation reaction is measured by two properties: (1) the thermodynamic driving force and (2) the rate constant of oxidation. The thermodynamic driving force of the oxidation process for one oxidant compared to another is determined by its oxidation potential. Table 31 is a list of the standard potentials E^0 for common chemical oxidants in aqueous solution at 298 K [265], [266].

Table 31. Standard electrode potentials for some common oxidizing agents in aqueous solution at 298 K [265], [266]

Oxidant	Half reaction	E^0, V
Oxygen [7782-44-7]	$O_2 + 4\,H^+ + 4\,e^- \rightleftharpoons 2\,H_2O$	1.23
Ozone [10028-15-6]	$O_3(g) + 2\,H^+ + 2\,e^- \rightleftharpoons O_2(g) + H_2O$	2.08
Chlorine [7782-50-5]	$Cl_2 + 2\,e^- \rightleftharpoons 2\,Cl^-$	1.36
Hypochlorous acid [7790-92-3]	$HOCl + H^+ + 2\,e^- \rightleftharpoons Cl^- + H_2O$	1.50
Hypochlorite	$ClO^- + H_2O + 2\,e^- \rightleftharpoons Cl^- + 2\,OH^-$	0.90
Monochloroamine [10599-90-3]	$ClNH_2 + H_2O + 2\,e^- \rightleftharpoons Cl^- + NH_3 + OH^-$	0.75
Chlorine dioxide [10049-04-4]	$ClO_2 + 2\,H_2O + 5\,e^- \rightleftharpoons Cl^- + 4\,OH^-$	1.71
Permanganate	$MnO_4^- + 4H^+ + 3e^- \rightleftharpoons MnO_2 + 2H_2O$	1.68
Hydrogen peroxide [7722-84-1]	$H_2O_2 + 2\,H^+ + 2\,e^- \rightleftharpoons 2\,H_2O$	1.78

The oxidation potential is a measure of a chemical's oxidizing (or reducing) power; the more positive the value of E^0, the more likely is the chemical reaction to take place as written. The parameter E^0 is related to the free energy ΔG^0 by the

formula $\Delta G^0 = -nFE^0$, where n is the number of electrons transferred and F is the Faraday constant (9.648×10^4 J/V). For example, the large positive value of E^0 (2.08 V) for Equation (10.1) below indicates that ozone is a powerful oxidizing agent.

The values in Table 31 are written as half reactions; thus, another half reaction is needed to complete the chemical equation. If the compound being oxidized by ozone is formate (Equation 10.2), the overall process would be as follows:

$$O_3(g) + 2H^+ + 2e^- \rightleftharpoons O_2(g) + H_2O \qquad E^0 = 2.08\ \text{V} \quad (10.1)$$

$$HCOO^- \rightleftharpoons CO_2(g) + H^+ + 2e^- \qquad -E^0 = 0.31\ \text{V} \quad (10.2)$$

$$O_3(g) + HCOO^- + H^+ \rightleftharpoons CO_2(g) + O_2(g) + H_2O \quad E^0_{net} = 2.39\ \text{V} \quad (10.3)$$

The overall chemical free energy change for the process represented by Equation (10.3) (i.e., the driving force) is calculated from

$$\Delta G^0 = nFE^0_{net} = -(2)(9.648\times10^4\ \text{J/V})(2.39\ \text{V}) = -461\ \text{kJ}$$

The large negative value of ΔG^0 indicates that the reaction should proceed spontaneously.

All common chemical oxidants shown in Table 31 are relatively powerful and should oxidize most organic compounds to carbon dioxide and water. The fact that this does not always occur (e.g., organic compounds on our planet are stable to oxidation by oxygen in most cases) indicates that thermodynamics is not the only important factor in determining whether a chemical reaction will occur spontaneously.

The other factor that is important in rating chemical oxidants is how fast they cause a chemical oxidation to proceed. This is the domain of chemical kinetics. In fact, in very few cases do the oxidants listed in Table 31 oxidize environmental contaminants as completely as would be expected from thermodynamic considerations. Chemical reactions that should occur, as indicated by the thermodynamic driving force, may do so very slowly if the rate constant for the process is low. For example, the reaction of formate with ozone is actually a very slow reaction, whereas that of another common pollutant, phenol, is very fast [267]. Another example is the rate of oxidation of two important natural products that contribute to bad taste and odor in water supplies: geosmin and methylisoborneol. The rates of chemical oxidation of geosmin and methylisoborneol by chemical oxidants vary substantially, making some impractical for use in water treatment. Of the common oxidants, ozone is more effective than others for the control of obnoxious taste and odor.

Chlorine. The solubility of chlorine in water is high compared to that of oxygen because in water, Cl_2 hydrolyzes to form hypochlorous acid:

$$Cl_2 + H_2O \rightleftharpoons HOCl + H^+ + Cl^- \quad (10.4)$$

Hypochlorous acid is a weak acid with a pK_a of 7.50 at 25 °C, dissociating to a hydrogen ion and the hypochlorite ion:

$$HOCl \rightleftharpoons H^+ + OCl^- \quad (10.5)$$

This means that at pH 7.50, equal amounts of HOCl and hypochlorite ion (OCl^-) are present. At higher pH, OCl^- predominates; at lower pH, HOCl. Hypochlorite ion is a weaker oxidant than HOCl (see Table 31) and also a weaker disinfectant. Both are powerful oxidizing agents as indicated by the E^0 values in Table 31, so aqueous chlorine is capable of oxidizing many organic and inorganic compounds [268], [269]. For example, chlorine has been used for years as a bleaching agent in pulp and paper treatment, for the oxidation of sulfides and cyanides, and for the oxidation of metals such as iron and manganese. Aqueous chlorine also reacts with organic compounds to substitute chlorine for hydrogen, which yields new chlorinated compounds (see Section Toxicology and Environmental Health). Chlorine is a toxic gas, and worker exposure must be avoided (⟶ Chlorine – Toxicology).

Chloroamines. Chloroamines are formed by reaction of chlorine with ammonia [268], [269]. The reaction occurs in three steps as shown below, leading to mono-, di-, and trichloroamines. These have slightly different oxidation potential and disinfection power, but in general, chloroamines are not as potent in both respects as chlorine. However, chloroamines are more stable in water than chlorine so they can maintain an active disinfection capacity for longer periods of time.

$$HOCl + NH_3 \rightarrow NH_2Cl + H_2O \quad (10.6)$$

$$HOCl + NH_2Cl \rightarrow NHCl_2 + H_2O \quad (10.7)$$

$$HOCl + NHCl_2 \rightarrow NCl_3 + H_2O \quad (10.8)$$

Ozone is always produced when oxygen is decomposed in air, e.g., in an electric discharge or when shortwave (<190 nm) UV radiation is absorbed by oxygen. This decomposition occurs naturally in the atmosphere, but it may also be used to generate ozone for water treatment by the reaction shown below using either air, oxygen-enriched air, or pure oxygen.

$$O_2 \xrightarrow{\text{Energy}} O^{\bullet} + O^{\bullet} \qquad (10.9)$$

$$O^{\bullet} + O_2 \rightarrow O_3 \qquad (10.10)$$

Ozone is more soluble in water than oxygen but less soluble than chlorine. In water it decomposes slowly, with a half-life that depends on the other substances present in water. Ozone is a toxic gas, and monitors are necessary where ozone is made and used, to minimize worker exposure.

Ozone is a powerful oxidant but reacts with different chemicals at various rates that range over several orders of magnitude. For example, the half-lifes of ozone's reactions with phenol and formate under similar conditions differ by a factor of about 100 000 [267]. Like chlorine, ozone has been used for the treatment of drinking water for disinfection, color and taste control and other purposes for over nine decades (ozone since 1906, installation at the Bon Voyage plant in Nice, France) [270]. Ozone has been more popular in Europe, especially France, than in North America, but this has been changing lately because of some of the environmental impacts of chlorine (see Section Toxicology and Environmental Health). Ozone alone is not always effective in oxidizing organic substances in water such as pollutants or taste and odor compounds, but its effectiveness may be enhanced by combining it with other oxidants (such as hydrogen peroxide) or with UV radiation [270].

Chlorine dioxide (⟶ Chlorine Oxides and Chlorine Oxygen Acids – Chlorine Dioxide) is a clear, colorless gas that dissolves readily in water without dissociation. It is a powerful disinfectant and oxidant (Table 31) and has been used extensively for water treatment. Chlorine dioxide is becoming an increasingly important alternative to chlorine as a bleaching agent in pulp and paper production. However, chlorine dioxide reacts rapidly with many substances in natural water, such as natural organic matter, in a reduction – oxidation reaction that produces chlorite ion (ClO_2^-). Chlorite has some documented health effects such as irreversible binding to hemoglobin, so the total amount of chlorine dioxide used in drinking water treatment is regulated in some countries (e.g., United States). Also, residuals of chlorine dioxide in drinking water have an objectionable taste and odor to some people.

Potassium permanganate has been used in water treatment for many years, primarily for oxidation of manganese(II) and iron(II) to the corresponding insoluble oxides or hydroxides, for color removal, and for taste and odor control. Potassium permanganate is usually not recommended for drinking water disinfection. Also, care must be taken not to overdose and produce a pink-colored water, which is objectionable to consumers.

Hydrogen peroxide (⟶ Hydrogen Peroxide) is a milder oxidant than chlorine or ozone. It is used in many industrial and medical applications as a mild disinfectant or oxidant, but worldwide its principal application is in wood pulping.

10.2. Production of Chemical Oxidants

Chlorine is produced in very large quantities worldwide, only a smal fraction of which is used for water treatment. Chlorine gas is produced mainly by electrolysis of brine (sodium chloride solution) according to the chlor – alkali, the mercury cell, or the diaphragm process (⟶ Chlorine, ⟶ Chlorine – Mercury Cell Process, ⟶ Chlorine – Diaphragm Process, ⟶ Chlorine – Membrane Process). Pure chlorine can be transported as liquefied gas and added to water under pressure, where it dissolves readily and hydrolyzes to hypochlorous acid and hypochlorite ion (see Eqs. 10.4 and 10.5). Commercial units are available to meter a specified amount of chlorine into water, usually into a slipstream which is then added to the total water stream to be treated so as to give the desired dose. Alternatively, aqueous chlorine (hypochlorite) may be prepared at the site of chlorine production and shipped to the location where it can be metered into the water to be treated. The latter is preferred in some highly populated areas where transport of gaseous chlorine is forbidden.

Chloroamines. The formation of chloroamines is carried out on-site by combining a chlorine solution with aqueous ammonia. To minimize byproducts, the chloroamines may be preformed by using an excess of ammonia so that no chlorine remains. A chlorine – ammonia weight ratio of 3: 1 corresponds roughly to the stoichiometric amount to form monochloroamine plus some dichloroamine, and a pH of 8.4 is optimal. Excess chlorine leads to the formation of trichloroamine, which has an objectionable taste.

Ozone is always produced on-site because it is an unstable gas that cannot be stored or shipped. Ozone is usually produced by an electric discharge in air, oxygen, or oxygen-enriched air (⟶ Ozone – Production). The most commonly used generators are of the silent discharge type in which discharge occurs across a dielectric barrier [270]. Small ozone generators may utilize discharge between ceramic electrodes or irradiation lamps.

Chlorine dioxide is also formed on-site, usually by reaction of sodium chlorite and chlorine (hypochlorous acid):

$$HOCl + 2\,ClO_2^- + H^+ \rightarrow 2\,ClO_2 + Cl^- + H_2O \qquad (10.11)$$

Commercial generators are available to regulate the ratio of chlorine and chlorite carefully or to recycle the stream so as to minimize the content of chlorine and byproducts in the product and to consume all of the chlorite ion. However, chlorine dioxide used in water treatment always contains some chlorite and usually chlorate, as well.

Potassium permanganate is produced by electrolysis of potassium manganate(VI) (K_2MnO_4), which is obtained by melting manganese dioxide and potassium hydroxide in the presence of air (⟶ Manganese Compounds – Fusion Processes , ⟶ Manganese Compounds – Anodic Oxidation of Manganate(VI)).

Hydrogen peroxide is usually produced from oxygen by using a catalytic process involving anthraquinone (⟶ Hydrogen Peroxide – Anthraquinone Process (AO Process)). It is marketed as a solution in water, usually containing 35 – 50 % H_2O_2. The compound is unstable, decomposing to oxygen and water by a reaction that is catalyzed by several substances, even

common soil. Hydrogen peroxide must therefore be shipped and stored in vessels made of passivated stainless steel, for example, in which it is more stable.

Mixed Oxidants. Oxidants are sometimes used in combination, the most common example being a mixture of ozone and hydrogen peroxide. These are always mixed at the site of application because the chemical reaction that occurs produces free-radical intermediates that have a very short lifetime (see Section Advanced Oxidation Processes).

10.3. Uses of Chemical Oxidants

Oxidants are used in water treatment for a variety of purposes, including disinfection and oxidation, in the treatment of drinking water and wastewater, oxidation in pulp and paper treatment, and disinfection and scale control in the treatment of cooling tower water.

10.3.1. *Drinking Water Treatment*

Chemical oxidants are used for treatment of drinking water, mostly for disinfection and removal of obnoxious chemical compounds or potential toxicants. The most common drinking water oxidant worldwide is chlorine (hypochlorous acid). In parts of Europe, ozone has been used for as long as chlorine, and it is growing in use worldwide.

10.3.1.1. *Disinfection*

Treatment with chemical oxidants has become the traditional method for disinfection of water for distribution in municipal water systems. Ozone and chlorine were first used for this purpose at about the beginning of this century and have been used continuously since that time [268], [269]. Chlorine is the more preferred of the two because it is more stable and maintains its disinfection capability for longer periods of time. Ozone decomposes quickly but is a more powerful disinfectant.

Drinking water sources can be classified generally as groundwater or surface water. Groundwater often does not require treatment except for disinfection, usually by addition of a chemical oxidant such as chlorine. In a drinking water plant for treating surface water, disinfection is accompanied by other unit processes such as coagulation (see Chap. Flocculation), sedimentation, and filtration (see Chap. Filtration). Also, the chemical oxidant that is applied as a disinfectant may be used to achieve other treatment objectives such as chemical oxidation (see Section Chemical Oxidation). The oxidant – disinfectant may be added at the beginning of treatment (peroxidation) or at other points in the treatment train. The amount of oxidant added and its contact time with the water are chosen such that the kill of microorganisms is highly efficient. At the end of the treatment train, a smaller amount of disinfectant (e.g., chlorine) is usually added so that water being sent to the customer will have a residual amount of disinfection protection. In Western Europe, the amount of residual disinfectant used is lower (≈0.1 mg/L) than is traditional in the United States (≈ 1 mg/L).

Disinfection efficacy is usually measured in terms of the dose (mg/L) of oxidant required to kill a certain fraction of a microorganism. Since the kill is also determined by the time the microorganism is exposed to the dose, the product of dose (C) times contact time (T) is an important process control parameter. In the United States, the Environmental Protection Agency has published values of CT for each disinfectant required to kill a certain fraction of various microorganisms. For tests used in other countries, see ⟶ Disinfectants – Efficacy Testing Methods, Requirements for Efficacy.

10.3.1.2. *Chemical Oxidation*

Oxidants are also used in drinking water treatment to remove substances that give unwelcome color to the water, compounds that cause poor taste or odor, and micropollutants that may have deleterious health effects. In addition, oxidants are used to remove iron and manganese, which are not toxic but may cause discoloration of household appliances.

Color in natural water is caused by natural organic matter (NOM) and sometimes by metallic elements complexed with NOM. Color is measured by comparison with a standard solution of a colored chemical compound such as chloroplatinic acid. The color of the water is expressed as “color units” (i.e., the amount of chloroplatinic acid necessary to give the same color). In drinking water plants using water sources that are highly colored, the water is usually treated with a chemical oxidant so that product water does not have a discernible color. Oxidants destroy color by chemically oxidizing the color center in the macromolecular NOM. Of the common chemical oxidants, ozone appears to be most effective for removing color. However, since the chemical structures in NOM that cause color vary from source to source, another oxidant may be more or less successful than ozone in removing the color, depending on the water source.

Taste and odor in water supplies are usually caused by chemical compounds produced by algae and other organisms but may also result from pollution due to industrial discharge. Again, the source of the bad taste or odor may vary from source to source, so a particular chemical oxidant may vary in its ability to remove the problem. Two compounds produced by algae, geosmin and methylisoborneol, are particularly obnoxious in that they can be sensed by humans at the ng/L level. Ozone is virtually the only common chemical oxidant that is effective in removing geosmin and methylisoborneol.

Iron and manganese are usually present in natural water. Higher oxidation states of both metals form rather insoluble hydroxides or oxides [e.g., $Fe(OH)_3$ and MnO_2], but lower oxidation states are more soluble (Fe^{2+} and Mn^{2+}). Therefore, these soluble forms are likely found under anoxic (reducing) conditions, such as in groundwater and below the hypolimnion in surface water. These substances are preferably removed in drinking water treatment before the water is sent to customers, where oxidation may cause precipitation of unwanted, colored oxides in plumbing. Oxidation of iron is a rapid reaction that can be accomplished easily in water treatment, even with molecular oxygen. All of the common oxidants can also easily oxidize Fe(II) to Fe(III), which is then precipitated and removed by filtration. Stronger oxidants are required for oxidation of Mn(II) to Mn(IV). Chlorine, potassium permanganate, and ozone are most commonly used, usually at the beginning of treatment prior to coagulation and sedimentation.

Micropollutants are synthetic organic or inorganic chemicals present in natural surface water sources because of discharges from industries, municipal waste treatment plants, and other sources. For example, surface waters in Europe and the United States are contaminated with agricultural chemicals, especially in the spring when herbicides are used in

abundance. Among the common oxidants, ozone is the most effective for removal of these and other organic micropollutants, but addition of hydrogen peroxide just before ozonation increases removal. The chemical mechanism responsible for the synergy between ozone and hydrogen peroxide is discussed in Section Advanced Oxidation Processes.

Groundwater may be contaminated with solvents, petroleum distillates, pesticides or herbicides, and other compounds that migrate into aquifers from spills, unwise use, and other human activities. A variety of treatment methods have been developed to clean contaminated groundwater, including activated carbon adsorption and air stripping. Oxidants may also be used to treat contaminated groundwater, but again the efficacy of treatment will vary depending on the molecular form of the contaminant. With regard to the most common groundwater contaminants, oxidation has been most successful in treating tri- and tetrachloroethylene, solvents that have leaked into reservoirs from storage tank, and accidental spills. The most successful oxidation methods for this purpose are ozone with hydrogen peroxide and ozone or hydrogen peroxide with UV radiation.

10.3.2. *Wastewater Treatment*

The use of chemical oxidants is not as common in wastewater treatment as in drinking water treatment because wastewater usually contains more impurities and, therefore, would consume more oxidants. Since oxidants are rather costly commodities, they are generally used for polishing (i.e., treating wastewater just before discharge) after most impurities have been removed [268], [269].

Chlorine has been used traditionally for treatment of domestic wastewater after biological treatment. The rationale was to minimize the concentration of microorganisms and ammonia being discharged into receiving streams. The chemistry of ammonia removal is essentially the same as that used to form chloroamines (see Section Physical and Chemical Properties of Chemical Oxidants), but in this case an excess of chlorine is added to oxidize the ammonia completely to nitrogen. This is referred to as *breakpoint chlorination*:

$$3\,HOCl + 2\,NH_3 \rightarrow N_2 + 3\,Cl^- + 3\,H^+ + 3\,H_2O \qquad (10.12)$$

Breakpoint chlorination of wastewater is still practiced, but concern over the chlorine byproducts produced is increasing so alternative oxidants such as ozone are gaining in favor.

10.3.3. *Oxidation in Pulp and Paper Treatment*

Chemical oxidants are used for bleaching pulp and paper (⟶ Paper and Pulp – Conventional Bleaching, ⟶ Paper and Pulp), and for decolorizing wastewater prior to discharge. Chlorine was the chemical oxidant of choice, but during the last two decades evidence of the formation of chlorinated byproducts including chlorinated dioxins and furans, has forced a reexamination of this practice. Of particular concern is the formation of chlorinated dioxins such as the highly carcinogenic 2,3,7,8-tetrachloro isomer. Modification of pulp and paper treatment is proceeding on a worldwide basis. Chlorine dioxide, oxygen, hydrogen peroxide, and ozone are being used instead of chlorine.

10.3.4. *Advanced Oxidation Processes*

The term advanced oxidation processes (AOPs) is used for water treatment processes that involve the formation of highly reactive, short-lived chemical intermediates. These intermediates (e.g., the hydroxyl radical) are powerful oxidants — more powerful than the conventional oxidants discussed above — and are used to oxidize water contaminants that resist other forms of treatment. Several AOPs have been developed and commercialized including the following:

1. Ozone in combination with hydrogen peroxide (sometimes called Peroxone process) with UV radiation, or with both hydrogen peroxide and UV
2. Hydrogen peroxide in combination with iron(II) salts (Fenton process), with UV radiation, or with UV radiation and other modifiers such as iodine ion, iron(III) salts, etc.
3. Oxygen in combination with high-energy, high-frequency sound waves (sonication), electron-beam irradiation, or gamma radiation

Oxidation with AOPs is used worldwide in the treatment of drinking water for oxidation of herbicides such as atrazine and simazine, and for oxidation of taste and odor compounds that are formed in rivers, lakes, and reservoirs. AOPs are also used in groundwater treatment to oxidize contaminants such as halogenated solvents (trichloroethylene and tetrachloroethylene). In addition, AOPs are being investigated for treatment of industrial wastewater, but they appear to be substantially more expensive than conventional biological treatment. Thus, AOPs may be most useful for treating low-volume streams containing compounds that are not easily biodegraded. In this case, oxidizing the target compounds only partially (i.e., not completely to carbon dioxide) may be most economical. Partially oxidized compounds are likely to be more easily biodegradable than their precursors, and the stream may then be given to a biological treatment unit process for final polishing before discharge into the environment.

Advanced oxidation processes that involve UV radiation utilize lamps such as mercury arc lamps that produce radiation of various wavelengths, depending on the power density of the current in the lamp. Low-pressure mercury arc lamps produce UV radiation primarily at 254-nm wavelength, whereas high-pressure lamps (operated at higher current densities and therefore at higher internal pressure and temperature) produce UV radiation with variable intensity at several different wavelengths from the visible region down to less than 200 nm. However, lamps are usually housed in quartz envelopes that cut off all radiation below 200 nm or, in the case of highly purified quartz, below 185 nm.

Low-pressure mercury arc lamps are suitable for disinfection of water because the 254-nm wavelength is absorbed by the DNA in bacterial and viral cells. This wavelength is also suitable for decomposition of ozone in the ozone – UV AOP, since ozone absorbs strongly at 254 nm. The following chemical equations summarize this complex process, which undoubtedly involves several steps not shown:

$$O_3 \xrightarrow{\text{UV radiation}} O^{\bullet} + O_2 \qquad (10.13)$$

$$O^{\bullet} + H_2O \rightarrow H_2O_2 \qquad (10.14)$$

$$H_2O_2 + 2\,O_3 \rightarrow 2\,OH^{\bullet} + 3\,O_2 \qquad (10.15)$$

$$OH^{\bullet} + \text{Organic contaminant} + O_2 \rightarrow \text{Partially oxidized byproducts} \qquad (10.16)$$

$$\text{Partially oxidized byproducts} + OH^{\bullet} + O_2 \rightarrow CO_2 + H_2O \qquad (10.17)$$

When ozone is used in combination with hydrogen peroxide, the last three equations summarize the chemical reaction.

High-pressure mercury arc sources are more suitable for other AOPs such as the H_2O_2 – UV process where UV radiation decomposes peroxide into OH radicals, which then oxidize water contaminants. The decomposition of hydrogen peroxide is described by the equations shown below:

$$OH^{\bullet} + \text{Organic contaminants} + O_2 \rightarrow \text{Partially oxidized byproducts} \qquad (10.16)$$

$$\text{Partially oxidized byproducts} + OH^{\bullet} + O_2 \rightarrow CO_2 + H_2O \qquad (10.17)$$

$$H_2O_2 \xrightarrow{\text{UV radiation}} 2\,OH^{\bullet} \qquad (10.18)$$

Similarly, when hydrogen peroxide is used in combination with iron(II) salts, OH radicals are produced by an oxidation – reduction reaction:

$$H_2O_2 + Fe^{2+} \rightarrow OH^{\bullet} + OH^{-} + Fe^{3+} \qquad (10.19)$$

The same radicals can be produced by direct decomposition of water by high-energy radiation or sonication:

$$H_2O \xrightarrow{\text{high-energy radiation}} OH^{\bullet} + H^{\bullet} \qquad (10.20)$$

As noted above, OH radicals in combination with oxygen oxidize organic contaminants in water eventually to form oxidized byproducts and, if enough oxidant is used, to form carbon dioxide and water. Whether the AOP is used to oxidize the contaminant completely is determined by economics.

10.4. Toxicology and Environmental Health

Chlorine and other chemical oxidants have had a very positive influence on human health because they are the principal disinfectants used in drinking water treatment, disinfection of sanitary facilities, and other applications. The incidence of waterborne diseases such as cholera and typhoid fever decreased dramatically in the early decades of the 20th century as water disinfection was practiced more extensively. In parts of Europe, particularly France, ozone served as the principal water disinfectant, whereas chlorine was preferred worldwide.

Chemical oxidants are generally toxic compounds themselves, so workers and the general public should be protected from large doses. However, low levels of oxidants, particularly chorine and chloroamines, are consumed regularly in drinking water with no apparent ill effects.

Disinfection Byproducts. In 1974, workers in the Netherlands and the United States discovered that chlorination of water produces a set of previously undetected byproducts known as the trihalomethanes (THMs) [271]. Trihalomethanes in this context usually mean four compounds: $CHCl_3$, $CHCl_2Br$, $CHClBr_2$, and $CHBr_3$, but other analogous containing mixtures of iodine, bromine, and chlorine (but not fluorine) as substituents are produced in low quantities. As a class, these compounds are called disinfection byproducts (DBPs). Subsequent studies showed that these and many other chlorinated and brominated byproducts are formed from the reaction of aqueous chlorine and the organic matter present in all natural water.

$$HOCl + NOM \rightarrow CHCl_3 + \text{Other chlorinated DBPs} \qquad (10.21)$$

$$HOCl + Br^{-} \rightarrow HOBr + Cl^{-} \qquad (10.22)$$

$$HOBr + HOCl + NOM \rightarrow \text{Mixed Cl — Br THMs} + \text{Other DBPs} \qquad (10.23)$$

Other chlorinated DBPs include halogenated acetic acids such as trichloroacetic acid and mixed chloro – bromo analogues, chlorinated acetonitriles such as Cl_2HCCN, halogenated aldehydes and ketones, and many others. Studies have shown that the yield of these compounds is generally in the microgram – milligram per liter range and depends on the concentration of NOM in the water, the pH, temperature, and chlorine dose.

Concern over the formation of DBPs was immediate because some of the compounds had previously been shown to be carcinogenic in test animals or to have other toxic effects. As a result, THMs are now the subject of water quality regulations in many countries, and maximum concentration levels are recommended by the World Health Organization. Depending on the country, the limit of THMs allowed in finished drinking water is in the range of 100 – 200 µg/L.

As a result of these regulations, which may be strengthened in the future, the use of chlorine in water treatment is being

reexamined. Many water treatment facilities are now using lesser amounts of chlorine; others have shifted to an alternative disinfectant such as ozone, chloroamines, or chlorine dioxide. However, all chemical oxidants react with naturally occurring compounds in water and form chemical byproducts [272]. For example, ozone reacts with naturally occurring bromide ion to form bromate ion, a substance that causes cancer in animal bioassays. The oxidation of bromide proceeds through the formation of hypobromite ion, which also may form byproducts on conversion to its corresponding acid form:

$$Br^- + O_3 \rightarrow BrO^- + O_2 \quad (10.24)$$

$$BrO^- + 2\,O_3 \rightarrow BrO_3^- + 2\,O_2 \quad (10.25)$$

$$BrO^- + H^+ \rightarrow HOBr \quad (10.26)$$

$$HOBr + NOM \rightarrow \text{Brominated Organic byproducts} \quad (10.27)$$

Chlorine dioxide and chloroamines form byproducts on reaction with NOM, although these products have not been as well characterized.

Other Oxidation Byproducts. Chemical oxidants used in wastewater treatment also form chemical byproducts and, in some cases, may affect the natural species in the receiving streams into which these waters are discharged. For example, residual ammonia in domestic wastewater is chlorinated to form chloroamines (see Section Physical and Chemical Properties of Chemical Oxidants). Chloroamines are toxic to fish and other aquatic organisms. In addition, chlorine may react with unidentified substances to form chlorinated dioxins, furans, furanones, and thiophenes. Some of these may have direct toxic effects, others may bioaccumulate in organisms and have long-term effects.

Oxidation byproducts may be produced even when oxidants are used in groundwater treatment. For example, oxidation of tri- and tetrachloroethylene, common groundwater contaminants, produces small amounts of chlorinated acetic acids, which may be more potent carcinogens than their precursors. Also, oxidation of simazine and atrazine, two common contaminants in surface water, produces various partially oxidized derivatives of the original compound.

In summary, all chemical oxidants form byproducts when they are used in water treatment. In some cases, such as drinking water chlorination, these byproducts have been well characterized and their toxicological properties are well known. World health authorities agree that the levels of these byproducts should be minimized, and regulations to do so have been promulgated in many countries. For other oxidants, very little information on the formation of chemical oxidation byproducts is available and further research is needed.

Finally, the risks from chemical byproducts formed by the use of oxidants as water disinfectants are rather low. Toxicologists estimate that the risk of obtaining cancer from the consumption of water containing chloroform at a concentration of 100 µg/L for a lifetime is only about 1 out of 100 000 – 10 000. In contrast, the absence of water disinfection can result in large outbreaks of microbiologically mediated diseases such as cholera, typhoid fever, and gastroenteritis. The risks of disinfection byproducts should always be compared with the risks of the microbiological species that disinfection removes [273].

1. Introduction

Waxes are among the oldest worked materials used by humans. Their value as versatile construction materials ("man's first plastic") was discovered very early. Today, waxes are used mostly as additives and active substances. The use of waxes is expected to increase in the future because of their generally favorable toxicological and ecological properties.

The historic prototype of all waxes is beeswax. Since it could be obtained with relatively little effort, it was popular in antiquity, and even now the term wax is occasionally used in everyday speech as a synonym for beeswax. However, the scientific and commercial definition of wax covers a much wider area.

1.1. History of Waxes and Their Applications

Utilization of waxes was probably begun in prehistoric times, but because of their transitory nature, no definite archaeological evidence exists. Thus, the utilization of wax and related substances in mummification and as protective coverings in ancient Egypt (from ca. 3000 B.C.) represents the earliest scientific proof of the use of waxes. Ancient written documents contain many indications that waxes found many different applications. The most well known is the story of Daedalus and Icarus, who used wax as an adhesive to make wings by attaching feathers to each other. In antiquity, wax was used as a raw material for modeling, in the production of casting molds, as a pigment carrier, and for surface protection.

In colonial times, hitherto unknown waxes, such as carnaúba, candelilla, and Chinese insect wax, were introduced in Europe. From the occurrence of wax, COLUMBUS inferred the riches of the Caribbean islands: "Where there is wax, there are also thousands of other things" [1].

For a long time, not much was known about the chemical nature of wax. Only in the 18th century did the discovery occur that beeswax is an animal secretion and not a plant product collected by bees. Wax research was established as a scientific discipline in 1823 [2]. It became part of the new research area of soaps, oils, fats, and waxes. The real breakthrough of wax as an important raw material, in terms of quantity as well, occurred at the beginning of the Industrial Revolution. Ozocerite (fossil wax) was mined and refined to give ceresin (1875), montan wax was obtained from Eocene lignite (1897), and paraffin waxes were obtained from crude petroleum. In 1935 the first fully synthetic waxes were produced by the Fischer – Tropsch process. Polyethylene wax has been synthesized by the high pressure process since 1939, and became available by the low-pressure Ziegler process after 1953. On a laboratory scale polyolefin waxes can also be synthesized by using modern metallocene catalysts.

Degradation processes for the production of waxes, which start from high molar mass plastics (mainly polypropylene), have also achieved a certain degree of importance. Finally, low molar

mass substances, which would otherwise have to be disposed of in plastics production, can be processed or refined to give industrially utilizable waxes.

A large and still increasing number of natural and synthetic waxes and related substances exists, as well as applications for these materials. No decrease in overall demand is apparent, so waxes are likely to remain important during the coming decades. The history of waxes has been described in great detail in [3].

1.2. Definition

No generally accepted definition exists for the term wax. All attempts to formulate a precise, comprehensive, and scientifically verifiable definition of wax must take the large number of waxlike products and the chemical complexity of individual types into account. Nevertheless, use of the term wax for different chemical species with common properties is still reasonable.

Typically waxes do not consist of a single chemical compound, but are often very complex mixtures. Being oligomers or polymers in many cases, the components differ in their molar mass, molar mass distribution, or in the degree of side-chain branching. Functional groups (e.g., carboxyl, alcohol, ester, keto, and amide groups) can be detected in waxes, sometimes several different groups.

The academic definition still quoted in chemistry text books – that waxes are esters of long-chain carboxylic acids with long-chain alcohols – is no longer useful. It applies fairly well only to some classical waxes, such as beeswax; others (e.g., petroleum waxes) do not fall in this category. Today, *physical* and *technical* definitions are preferred. Several attempts were made to differentiate between waxes and other classes of substance, particularly fats, resins, and high molar mass polymers, by using several criteria. These primarily *physical* definitions are to some extent arbitrary and are not generalled accepted. Waxes can also be classified according to their *applications*.

Probably the most conclusive definition has been drawn up in Europe by the Deutsche Gesellschaft für Fettwissenschaft (DGF, German Association for Fat Science). It was used in modified form in the customs tariff of the European Union [4], [5]. According to this definition, waxes must have:

1) A drop point (mp) >40 °C
2) Their melt viscosity must not exceed 10 000 mPa · s at 10 °C above the drop point
3) They should be polishable under slight pressure and have a strongly temperature-dependent consistency and solubility
4) At 20 °C they must be kneadable or hard to brittle, coarse to finely crystalline, transparent to opaque, but not glassy, or highly viscous or liquid
5) Above 40 °C they should melt without decomposition
6) Above the *mp* the viscosity should exhibit a strongly negative temperature dependence and the liquid should not tend to stringiness
7) Waxes should normally melt between ca. 50 and 90 °C (in exceptional cases up to 200 °C)
8) Waxes generally burn with a sooting flame after ignition
9) Waxes can form pastes or gels and are poor conductors of heat and electricity (i.e., they are thermal and electrical insulators).

In the case of higher molar mass polyolefin waxes, differentiating between a wax and a thermoplastic polymer is sometimes difficult. This differentiation is particularly important for applications where a food approval is essential (FDA, EC, MITI in Japan, etc.). In case of doubt, relevant national regulations must be consulted.

1.3. Classification

Waxes can be classified according to various criteria such as origin; chemical, physical, and engineering properties; or applications (see Section 1.2). The primary differentiation is usually made according to origin or occurrence and synthesis. A proposal for a classification is shown in Figure 1. Here, waxes are divided into two main groups: natural and synthetic. Natural waxes exhibit their wax character without chemical treatment, whereas synthetic waxes generally acquire their waxy nature in the course of synthesis. There are no clear borderlines.

Figure 1. Classification of waxes

Natural waxes are formed through biochemical processes and are products of animal or plant metabolism. Natural waxes formed in earlier geological periods are known as *fossil waxes*. All petroleum, lignite (montan wax), and peat waxes belong to this largest category. Fossil waxes occur predominantly as minor components of oil, coal, and peat. Some deposits with a high wax content were formed by sedimentation. *Ozocerite* separated from oil, and *pyropissite*, one of the few organic minerals, is a mixture of montan wax and resins. Whereas petroleum waxes are predominantly nonpolar hydrocarbons, lignite and peat waxes consist of oxygen-containing compounds.

Biological wax synthesis is still taking place in nature. Many plants, particularly carnaúba palm, and animals – most importantly insects, such as bees – produce waxes. These are known as *nonfossil* or *recent natural waxes.* Natural waxes are seldom used industrially in their original form. They are generally converted into *modified natural waxes* by refining, e.g., by distillation, or extraction. Chemical processes, such as hydrogenation, bleaching, and oxidation, can also be used. Physical and chemical treatment can be combined; the objective of all these processes is to obtain a wax that is as pure as possible.

Partially Synthetic Waxes. If natural waxes or waxlike materials are modified by chemical reactions such as esterification, amidation, or neutralization of acidic waxes (with aqueous alkali or alkaline-earth metal hydroxides), partially synthetic waxes are obtained. These can be tailored to particular applications. In *esterified waxes* the relationship to natural waxes is still easily recognizable. For example, natural montan waxes, which consist mainly of esters of long-chain acids with long-chain alcohols, can be converted into acid waxes by cleavage of the esters and oxidation of the alcohols. Subsequent reaction with dihydric alcohols gives es-

ters that have chemical structures comparable to those of the starting materials. *Amide waxes* do not occur naturally to any significant extent. This group consists of reaction products of fatty acids with ammonia, amines, and diamines. An industrially important amide wax is distearoyl ethylenediamine.

Alcohol waxes (*lanette waxes*) also belong to the partially synthetic waxes. They are mixtures of long-chain alcohols that are optimized for their main area of use, in ointments and creams for pharmaceuticals and cosmetics, by the addition of fatty acid esters and emulsifiers. Alcohol waxes can also be used for industrial emulsions with good long-term stability.

Wool wax (*lanolin*) is obtained in crude form from sheep's wool. It is refined by chemical and adsorptive bleaching, and sometimes by subsequent hydrogenation or separation of the acidic fractions after hydrolysis. Wool wax is a mixture of esters, some being derived from branched or cyclic waxy or fatty acids and alcohols.

Fully synthetic waxes were developed only in the 20th century. Low molar mass compounds are used as starting materials. The products can be waxes in the narrower sense of the definition (see Section 1.2), or substances with only partial wax character. The two main groups of fully synthetic waxes are the Fischer – Tropsch and the polyolefin waxes. These waxes can be classified according to the starting material used for production (C_1 or C_2 chemistry).

C_1 Building Blocks. The Fischer – Tropsch (FT) synthesis is described elsewhere in detail (→ Coal Liquefaction, Chap. 2.2.). The oldest FT variant is the ARGE process (Arbeitsgemeinschaft Ruhrchemie – Lurgi). Synthesis gas is obtained by reaction of steam with carbon (→ Gas Production, Chap. 4.) and is then converted catalytically into a broad spectrum of saturated and unsaturated hydrocarbons. Among these products are the Fischer – Tropsch waxes. They are characterized by low branching of the hydrocarbon chain and a narrow molar mass distribution. They are relatively hard products. The ARGE process has been used commercially by SASOL in the Republic of South Africa.

Besides carbon, natural gas can also be used as a raw material for C_1 syntheses. The Shell Middle Distillate Synthesis (SMDS) process utilizes synthesis gas produced by steam reforming of natural gas [6]. Fischer – Tropsch wax fractions are produced and marketed at the new SMDS plant in Bintulu (Sarawak/Malaysia). This process is a variant of the classical FT process and employs specially developed catalysts.

Polyolefin waxes are, in most cases, products of C_2 or C_3 chemistry. Low molar mass α-olefins, usually ethylene, are polymerized. The other route to polyethylene waxes – thermomechanical degradation of polyethylene plastic – is now of minor importance. The two most important production processes are the high-pressure and the Ziegler processes. More recently, polyolefin waxes have also been synthesized by using modern metallocene catalysts.

Polyolefin waxes can be homopolymers or copolymers of C_2, C_3, C_4 (ethylene, propene, and butene), or higher α-olefins. Polypropylene (PP) waxes are produced by the Ziegler process or by thermomechanical degradation of polypropylene plastic. Polypropylene waxes are generally partially crystalline. In addition, predominantly amorphous and atactic low molar mass polypropylene (APO or APAO) with a waxlike character is now produced and marketed by several companies. Besides this deliberate production, atactic PP (APP) is still produced as a byproduct of PP plastics.

All FT and polyolefin waxes are nonpolar. Polar waxes are obtained by subsequent reactions, such as oxidation by air or grafting (e.g., with maleic anhydride), optionally followed by neutralization to metallic soaps, esterification, or amide formation. Polar polyolefin waxes are also accessible via direct copolymerization or addition reactions (e.g., of olefins with unsaturated carboxylic acids or esters).

A considerable proportion of industrially processed waxes is used not in pure form but as wax compounds. For example, the viscosity and *mp* of paraffin waxes can be increased to the desired degree by mixing with polyolefin waxes.

1.4. Properties and Uses

The number of possible and actual uses of waxes is extraordinarily high. The physical and chemical properties of various types of wax can be combined fairly freely through mixtures and preparations. Therefore, waxes are represented

in almost all possible areas of use, although to differing extents. Any selection of applications thus has to be somewhat arbitrary.

For the user, the application-oriented function of the wax is important, not so much its chemical structure. The latter is defined primarily by the characteristic hydrocarbon chain, the basic building block of almost all waxes. It imparts hydrophobing properties to waxes. The carbon chain length of fatlike waxes is $n = 16 - 18$ (e.g., amide wax); for esterified and paraffin waxes, $n = 20 - 60$; and for polyethylene waxes, less than hundred to several thousand. Besides the chain length itself (and thus the molar mass), molar mass distribution and degree of branching also affect the properties of waxes. The melting and softening points, melt viscosity, and degree of hardness increase with increasing chain length. High degrees of branching lower the *mp* and the hardness. Polar groups, such as carboxyl, ester, and amide groups, strengthen intermolecular forces and generally raise the *mp* and hardness.

Particular features of many waxes are their good absorption capacities and their ability to bind solvents. Hot wax solutions form stable, homogeneous pastes on cooling. These can be applied to surfaces and polished after evaporation of the solvent. The resulting wax films are shiny or glossy, hard, and resistant to mechanical stress.

When a suitable emulsifier is added, *polar waxes* can form fine stable dispersions in water. Mixed aqueous – organic emulsions can also be produced. These mostly stable dispersions and emulsions are used for surface protection. After application, the wax-containing phase dries and a protective, sometimes even glossy, coating is formed.

In addition to surface protection, hydrophobing, and gloss-giving, other functions of waxes include surface protection, hydrophobing, gloss-giving, matting, mold releasing, lubricating, binding, imparting compatibility or flexibility, regulating viscosity, adjusting consistency, emulsifying, dispersing, and adjusting drop points. Waxes are also used as combustible and illuminating materials.

For special applications only a few – frequently only one – of these functions are important. Some occasionally opposite effects are noteworthy: wax gives polish and gloss to various surfaces but has a matting effect as an additive in paints and coatings. Waxes are used as binders in master batches but as release agents in molding plastics. Table 1 gives some idea of the versatility of waxes but does not claim to be complete. For the specific suitability of waxes to individual applications, monographs, company brochures, and prospectuses should be consulted.

Table 1. Branches of industry in which waxes are used

Branch	Examples of applications
Adhesives, hot melts	viscosity regulation, lubricants, surface hardening
Building	modification of bitumen, antigraffiti treatment
Candles	fuel, drop point regulation
Ceramics and metal	binders for sintering
Cosmetics	binders and consistency regulators for ointments, pastes, creams, lipsticks
Electrical and electronics industries	release agents, insulating materials, etching bases
Explosives	stabilization
Foods	citrus fruit and cheese coating, chewing gum base, confectionery
Matches, pyrotechnics	impregnation, fuel
Medicine and pharmaceuticals	molding and release agents in dental laboratories, retardants, surface hardening of pills
Office equipment	dispersing agents and binders for carbon paper and selfduplicating paper; antioffset for toners for photocopiers
Paints and coatings	matting, surface protection
Paper and cardboard	surface hardening
Plastics	lubricants (PVC ∗), release agents (PA ∗∗), pigment carriers (masterbatch)
Polishes	surface protection of leather, floors, cars
Printing inks	improvement of rub resistance, slip
Recycling	compatibilizing
Rubber industry	release agents enhancing rigidity, surface hardening

∗ PVC = poly(vinyl choride).
∗∗ PA = polyamide.

1.5. World Market Volume for Waxes

No reliable global capacity or production data are available for waxes. The main reasons for this are the many types of wax and the difficulties in differentiating among them; the comparatively low transparency of the market; and the dependence of wax production on external factors, such as crude petroleum consumption and annual harvest of natural waxes. Some statistical

data exist for certain markets (e.g., the United States [7]). Thus, the following figures can be regarded only as rough indications, with a correspondingly large degree of fluctuation, of the magnitude of annual worldwide wax consumption data:

Paraffin waxes, including microcrystalline waxes	3 000 000 t/a
Polyolefin waxes including oxidates and copolymers	200 000 t/a
Fischer – Tropsch waxes	100 000 t/a
Amide wax	50 000 t/a
Montan wax including crude montan wax	25 000 t/a
Carnaúba wax	15 000 t/a
Beeswax	10 000 t/a
Candelilla and other plant waxes	3 000 t/a

Forecasts for future market development anticipate positive growth factors. Specialties, such as special waxes or compounds for critical applications (e.g., in the electrical, electronics, or ceramics industries), will probably profit more from this development than waxes, that are tend to be continuously replaced in their applications. The decreasing demand for waxes in the packaging sector, for example, is becoming noticeable. The proportion of waxes used in some other classical applications (e.g., carbon paper) is continually declining. However, waxes generally have favorable ecological and toxicological properties, in addition to the variety of applications described, so their market chances may outweigh the risks in the long term.

1.6. International Wax Organizations

In Europe the interests of all wax producers have been represented by the European Wax Federation since 1979 (EWF, Avenue van Nieuwenhuyse 4, Brussels, Belgium). The EWF is a member of the Conseil Européen des Federations de l'Industrie Chimique (CEFIC) and is open to all European wax producers and some outside Europe. It represents the interests of its members, with regard to both technical questions such as specifications and legal matters referring in particular to the European Union. In other regions, no organizations exist that cover the entire wax spectrum.

2. Recent Natural Waxes

2.1. Introduction

Many plant and animal organisms produce waxes with extraordinarily complex compositions. The main components are usually those that correspond to the classical definition of waxes – i.e., esters of long-chain aliphatic alcohols and acids, which belong to homologous series in the ca. $C_{16} - C_{36}$ (predominantly $C_{22} - C_{36}$) range, those with an even number of carbon atoms predominating. Recent natural waxes also contain smaller quantities of esters derived from acids and alcohols with an uneven number of carbon atoms as well as bifunctional components such as diols, hydroxycarboxylic, and dicarboxylic acids. Natural waxes contain very small proportions of branched carboxylic acids, mainly those with ω-methyl branching. Aromatic acids, such as cinnamic, 4-hydroxycinnamic, and ferulic (4-hydroxy-3-methoxycinnamic) acids, have also been found in some waxes. Because of the presence of bifunctional components, natural waxes can contain not only the simple, classical wax esters, but also oligoesters with two or more ester functions and other functional groups in the molecule.

Free acids and alcohols are present in natural waxes in widely varying quantities. They are generally identical to those present as ester components.

Homologous *n*-alkanes in the ca. $C_{15} - C_{37}$ range, mainly those with an uneven number of carbon atoms, are also components of natural waxes in proportions of 1 – 50 %. Branched-chain and olefinic hydrocarbons are present in insignificant quantities. Glycerides (fats), phytosterols, terpenes, resins, long-chain carbonyl compounds, and flower pigments are also present in very small proportions. Because of the complex mixtures involved and the relatively simple analysis techniques of earlier years, the inconsistency of literature data on the composition of natural waxes is understandable.

Modern analytical instruments are required for complete analysis of a natural wax. High-temperature capillary GC, possibly coupled to a mass spectrometer, is a suitable the best analytical method.

Beeswax and carnaúba and candelilla waxes have a total annual market volume of ca. 28 000 t worldwide. These are economically the most important natural waxes [8].

Among the large number of other known waxes, ouricury, esparto, bamboo, and Japan wax (actually a special vegetable tallow) are of regional or local importance. Their availability is estimated to be 3000 – 4000 t/a [8], [9].

In all areas of application for waxes, recent natural waxes are now mostly used together with modified fossil and synthetic waxes. Applications include preparations for cleaning, polishing, and preserving floors, furniture, and car bodywork surfaces; the candle industry; craft work; production of pharmaceuticals, cosmetics, and confectionery (observing appropriate legal approval); metal and ceramic sintering technology; coating techniques; the paint and coating industries; and the production of carbon paper compounds. The latter, which was important in terms of quantity, has been replaced almost completely by new duplicating processes. Despite the market recession this has caused [10], an annual growth of ca. 4 % is expected in the U.S. market for natural and synthetic waxes [11].

Special, ion-free or low-ion natural wax raffinates have also been used in electronics.

In his standard book *The Chemistry and Technology of Waxes*, A. J. Warth included a comprehensive chapter on all known recent natural waxes. The second edition of the book was published in 1956 and is currently out of print [12].

2.2. Vegetable Waxes

In contact with the environment, plants form a compressed epidermis on their surfaces by depositing secondary layers of cellulose, except in the case of inflorescence [13]. This mechanical reinforcement is supplemented by deposition of cutin in the outer epidermal layers and an outer coating of cutin (cuticula) to regulate water content. As a result of climatic conditions, many plants in tropical regions also store waxes in cutinized membrane layers in the cuticula as an additional protection against evaporation of water. In many cases, waxes exude outward and form wax coatings, which can be up to several millimeters thick. Xerophytes, plants found in exceptionally arid regions, are however not the greatest wax producers [14]. Specific soil types, temperature, dry periods, and heavy rainfall, as well as temporal changes in these, are responsible for enhanced wax formation. Vegetable waxes can be classified according to their origin as deciduous and coniferous tree waxes, shrub and herb waxes, and grass and flower waxes, and within these groups into leaf, needle, stem, and root waxes; bark and skin waxes; and seed and fruit waxes.

2.2.1. Carnaúba Wax

The leaf wax of the carnaúba palm is by far the most important recent vegetable wax both economically and with regard to applications [12], [13], [15], [16]. The carnaúba palm is a fan palm found mainly in Brazil and given the botanical name *Copernicia cerifera* by v. Martius in 1819 in honor of the astronomer Copernicus. It was apostrophized as the life tree of Brazil by v. Humboldt.

History. The existence of carnaúba wax was first reported in 1648 [17], and some data concerning its composition were published in 1811 in *Transactions of the Royal Society, London*.

In 1836 the Brazilian Macedo arranged for chemical investigations to be carried out on carnaúba wax at the Sorbonne in Paris. He began small-scale extraction and purification of carnaúba wax in 1856. In 1862, 1280 t of carnaúba wax was exported from Brazil.

Occurrence and Isolation. The carnaúba palm occurs mainly in north eastern Brazil in the provinces of Bahia, Rio Grande do Norte, Paraiba, Pernambuco, and particularly Ceara and Piaui, where there is a total stand of ca. 90×10^6 palms in a surface area of 10^6 km^2 [18], [19]. Smaller areas exist in southern Brazil, northern Argentina, Paraguay, and Bolivia. Different climatic conditions in other tropical and subtropical countries, in which carnaúba palms were planted as an experiment, allow satisfactory growth but markedly reduced formation of wax deposits on the leaves.

The palms grow to a height of 6 – 12 m, occasionally to 20 m, and are said to achieve a lifetime of up to 200 years. When the palm has reached an age of ca. eight years, one leaf gives a wax yield of 5 – 7 g, which is worth harvesting. The annual yield of wax per palm is ca. 150 g.

To isolate the wax, ca. 20 – 30 leaves at different stages of development are removed from each palm twice a year (September and December) [12].

The unopened heart leaves, of which only a few are removed per palm, carry particularly light-colored wax (prime yellow). Wax on the outer palm leaves is yellow, gray-green, or gray-brown, depending on climatic conditions during the vegetation period and on leaf age.

After drying the leaves in the sun or on steam-heated racks, the wax is chipped off manually or nowadays mostly by machine. The primary purification process involves melting over water and gives a crude wax that can be purified further by centrifugation, filtration with additives, or solvent extraction. Additional bleaching with hydrogen peroxide is also carried out.

The central ribs are often removed from the leaves before drying. The dried leaves are then chopped and the chips separated by air classification to give a mixture of ca. 60 % wax and 40 % chopped plant, which is stirred with water and oxalic acid to form a paste. The latter is heated to its boiling point and pressed through a filter while hot. Centrifugation of the filtrate gives virtually anhydrous wax. The remaining wax is extracted from the dried filter cake with aliphatic hydrocarbons (e.g., heptane).

The crude product is normally supplied in lumps that are obtained by breaking up the wax blocks into which the melt was cast. Carnaúba wax is also sold now in other forms.

Types. Internationally recognized classifications and specifications for genuine, unfalsified types of carnaúba wax were worked out by the American Wax Importers and Refiners Association according to established methods of determination [20].

The classification used in Brazil, shown in Table 2, has been valid worldwide since the beginning of the 1980s.

The highest-value type, *T 1*, is a prime yellow wax purified by filtration. To obtain *T 3*, suitable crude waxes (colored) are filtered and then bleached with hydrogen peroxide. The *T 4* wax is exported predominantly in the form of centrifuged or filtered variants.

Chemically refined or derivatized carnaúba waxes are no longer available commercially because of lack of demand [8]. Chemical refining processes, such as heating with alkali in the presence of paraffins, gave carnaúba wax residues in addition to the corresponding raffinates [21–27]. Where these processes are used, they account for <1 % of the total volume of carnaúba wax.

Properties. Carnaúba wax is one of the hardest and highest-melting natural waxes. Because of its fine crystalline structure, its fracture edges are smooth and have a macroscopically homogeneous structure. At room temperature the wax has a weakly aromatic odor and a characteristic haylike scent (similar to coumarin) in the molten state [28]. Carnaúba wax is compatible with almost all natural and synthetic waxes and a number of natural and synthetic resins. It is readily soluble in most nonpolar solvents on warming [12] and is miscible with them in all proportions above its *mp*. On cooling, the wax precipitates from solution to form a solid paste. Carnaúba wax is only partially soluble in polar solvents, even on warming, and is generally sparingly soluble at room temperature (0.15 – 0.6 %) [12].

Melting, solidification, and drop points as well as hardness of other waxes increase on addition of small quantities of carnaúba wax. With paraffins, the addition of carnaúba wax suppresses their tendency toward coarse crystallinity and reduces possible tack in the case of soft waxes.

Composition. Many analyses of carnaúba wax has been carried out, with conflicting results [12], [14], [15]. According to a thorough investigation, carnaúba wax prime yellow (T 1) has the composition given below [29]:

Aliphatic esters	40.0 wt %
Diesters of 4-hydroxycinnamic acid	21.0 wt %
Esters of ω-hydroxycarboxylic acids	13.0 wt %
Free alcohols	12.0 wt %
Diesters of 4-methoxycinnamic acid	7.0 wt %
Free aliphatic acids	4.0 wt %
Free aromatic acids	1.0 wt %
Hydrocarbons (paraffins)	1.0 wt %
Free ω-hydroxycarboxylic acids	0.5 wt %
Triterpene diols	0.5 wt %
Unsaponifiable components	56.4 wt %
Saponifiable components	39.2 wt %
Aromatics and/or resins	4.4 wt %

The aliphatic esters contain monocarboxylic acids of average chain length C_{26} and mono-

Table 2. Carnaúba wax types and specifications

Characteristic	T 1 (prime yellow)	T 3 (fatty gray/light)	T 4 (fatty gray/crude)	T 4 (fatty gray/centrifuged)	T 4 (fatty gray/filtered)

∗ Values based on 100 % total acid, total alcohols, and total paraffins in each case (deviations from 100 % = sum of all other acids and alcohols).
∗∗ Approximate.

Esters containing 4-hydroxy- and 4-methoxycinnamic acids are present mainly as oligomers and polymers. The monomer units of these are diesters of the above-named cinnamic acids with mono- and polyhydric alcohols and ω-hydroxycarboxylic acids.

The free alcohols are similar in composition to those in aliphatic esters. The wax also contains a small proportion of secondary alcohols.

The even-numbered *n*-monocarboxylic acids, *n*-monohydric alcohols, and *n*-alkanes present in all carnaúba wax types have typical, distinctive chain-length distributions (see Table 3).

The important difference between Type 1 carnaúba wax and the other types is that the latter contain no triterpenediols and the esters of 4-hydroxy- and 4-methoxycinnamic acids have higher degrees of polymerization compared with Type 1. This may be attributed partly to differences in climate but also to the fact that Type 1 is harvested from genetically younger leaves, whereas the others come from older leaves that have been exposed to more sunshine.

Uses.

T 4 Variants. The wide use of carnaúba wax in the production of *preserving and cleansing agents* for floors (floor polishes, ionogenic and nonionogenic day-bright emulsions, wiping waxes and cleaners, sealing emulsions, spray cleaners, etc.); and polishes for furniture, cars, and shoes (solvent – water or straight solvent products) is based on its ability to form pastes and glossy and repolishable films and its ability to be dispersed. In this classical area a large proportion of T 4 variants of carnaúba wax are used.

Type 1 carnaúba wax and some of Type 3 (after absorptive purification to remove peroxide components arising from hydrogen peroxide bleaching) are approved for use in the *pharmaceutical industry* (e.g., as polishes for pills) and the *cosmetics industry* (as lipsticks and lip salves).

In the *food sector*, T 1 and T 3 waxes are used as release agents for bakery and confectionery products and as additives in chewing gum production.

In *polymer processing*, carnaúba wax is used in release agent preparations and, to a small extent, as a lubricant. The *varnish industry* uses carnaúba wax as an additive in the interior coating of food containers [8].

In the *leather industry*, carnaúba wax is used for cutting waxes, cleaning waxes, and edging inks. It is also approved for coating citrus fruit.

Economic Aspects. About 10 000 – 16 000 t/a carnaúba wax is available worldwide, of which ca. one-fifth is Type 1. Brazil, the sole exporter, supplies mainly Europe (ca. 2000 t/a), the United States (3000 – 4000 t/a), and Japan [8]. About 3000 – 3500 t/a is for indigenous supply.

Carnaúba wax consumption in the United States decreased markedly from 1955 to 1976 and then remained constant [9]. Brazil is increasingly exporting purified or bleached products in flaked form to achieve higher prices. Harvests, exports, and price structuring are subject to government control.

Waxes with Similar Compositions. *Copernicia australis*, a palm that produces large quantities of leaf wax, is found in Paraguay and around its border with Argentina (Gran Chaco). It is similar to *Copernicia cerifera* in many respects. A few small factories for isolating this palm wax are said to have been erected since 1945 [30].

The Brazilian *cauacu bush*, found mainly in Pará province and by the upper Amazon, produces a wax that is said to be similar to carnaúba wax in chemical composition. However, the wax is isolated only sporadically and to a limited extent [31].

2.2.2. Candelilla Wax

Occurrence and Isolation. The climatic conditions of the semideserts in southern California, Arizona, south western Texas, northern Mexico, and parts of Central and South America favor enhanced wax formation in *Euphorbia* (*E. cerifera, E. antisyphilitica*) and *Pedilanthus* (*P. pavonis, P. aphyllus*) species. The wax deposited on the stalks and leaf stems of these plants, which grow as bushes or shrubs, is known as candelilla wax [12], [14], [32], [33].

Numerous and dense stands of these plants are found mainly in northern Mexico in the states of Chihuahua, Coahuila, Durango, Nuevo León, San Luis Potosi, Tamaulipas, and Zacatecas over a total area of more than 100 000 km^2. These are the only areas in which candelilla wax is obtained [34].

In manual harvesting the plants are pulled out, leaving most of the root system in the soil. Together with scattered seeds, roots remaining partially in the soil guarantee the growth of new stands, which takes several years.

In collecting and processing locations, plant material is boiled with ca. 0.2 % sulfuric acid in open vessels, which are heated using already dewaxed and dried stalks. Metal grids keep the plants under the surface of the liquid, and addition of sulfuric acid inhibits emulsification of the wax. The latter collects in molten form on the surface of the liquid. After the wax is skimmed off into open vats or barrels, it solidifies to form the crude wax known as cerote. Yields based on plant material are 3 – 4 %.

Wax from outer areas of the solidified wax blocks is removed with impurities that have concentrated there and is subjected to the boiling process again. The remainder of the wax is purified in a central refinery located in Saltillo by melting with sulfuric acid and filtering in filter presses. The crude wax broken down into lumps is the Mexican commercial product (Mexican Standard Grade Candelilla Wax).

Candelilla wax raffinates are obtained from crude wax by adsorptive purification or hydrogen peroxide bleaching. They are produced and sold in the United States and Europe. The properties of these products, apart from color, are identical to those of crude candelilla wax.

Following the transfer of Mexican candelilla wax production from state monopoly to private

enterprise, candelilla wax raffinates produced in Mexico will also be put on the market [8].

By deresinification and subsequent oxidative chromic acid bleaching, products that are almost white can be obtained. Because of the high price of genuine wax, these processes have no practical importance.

Properties and Composition. Candelilla wax is a hard, brittle wax that is very similar to carnaúba wax with regard to solubility in polar and nonpolar organic solvents. A large proportion of the resin present in the wax can be extracted at room temperature with hot 70 % ethanol, acetone, or low-boiling, chlorinated organic solvents.

The *physical and chemical properties*, the color (brown – brownish yellow – pale yellow), and the degree of purity vary depending on climate, time of harvest, region, and age of harvested plants. The recognized specification for genuine crude candelilla wax is given in the following [34].

mp	68.5 – 72.5 °C
Refractive index	1.4550 – 1.4611
d_4^{15}	0.950 – 0.990
Acid number	12 – 22 mg KOH/g
Saponification number	43 – 65 mg KOH/g
Hydrocarbon content	30.6 – 45.6 %
Total acid content	20.6 – 29.0 %
Color	amber
Flash point	235.4 – 248.4 °C
Components insoluble in xylene/toluene (1 : 1)	0.0 – 0.1 %

The data agree with those previously laid down by the American Wax Importers and Refiners Association for prime crude candelilla wax [20].

The average *composition* of candelilla wax gives below is derived from the large number of values found in the literature.

Hydrocarbons (ca. 98 % paraffins + 2 % alkenes)	42.0 wt %
Wax + resin + sitosteroyl esters	39.0 wt %
Lactones	6.0 wt %
Free wax and resin acids	8.0 wt %
Free wax and resin alcohols (terpene alcohols)	5.0 wt %
Saponifiable components	23.0 – 29.0 wt %
Unsaponifiable components	71.0 – 77.0 wt %

Candelilla wax differs fundamentally from carnaúba wax in its high hydrocarbon content of 45 % (max.) and resin content of 20 %. Whereas carnaúba wax contains >80 % wax according to the classical chemical definition, candelilla wax consists of <35 % of these components.

As in all natural waxes, in candelilla wax the paraffins and wax acids or alcohols with even-numbered carbon chains have typical and distinctive chain-length distributions (Table 4).

Table 4. Chain-length distribution of even-numbered carboxylic acids and alcohols, and paraffins in candelilla wax

Chain length (C-number)	Acids ∗, % (approx.) ∗∗	Alcohols ∗, % (approx.) ∗∗	Paraffins ∗, % (approx.) ∗∗
22	0.3		
23			
24	0.1		
25			
26	0.3	2.4	0.1
27			0.2
28	3.2	17.4	0.5
29			5.6
30	36.4	58.0	1.3
31			80.0
32	48.6	19.0	1.8
33			9.0
34	8.0		0.2

∗ Values based on resin-free total acid, total alcohol, and total paraffin (deviations from 100 % = sum of all other acids, alcohols, and hydrocarbons).
∗∗ Approximate.

Uses. Candelilla wax is used in classical *cleaning preparations and polishes* (e.g., as a component of shoe and other leather polishes) and in furniture, car, and floor polishes. Because of its particular composition, this wax can be used in the applications only in combination with other suitable natural and synthetic waxes. Its use in floor polish is very limited because the high resin content leads to increased dirt pickup.

Candelilla wax is also used in the production of *candles, coatings* for paper and cardboard, *hotmelt adhesives*, and in *polymer processing*.

It is also approved for use in the *cosmetics*, *pharmaceutical*, and *food industries*. The main use of candelilla wax, principally in the United States and Europe, is by the cosmetics industry in the production of lipstick. Here, properties such as outstanding framework formation with castor oil, gloss, and uniform shrinkage on cooling (very good demolding after casting lipsticks) are very important [8]. Candelilla wax is also

used as a polish for pills and in the production of chewing gum and confectionery.

Economic Aspects. For nomadic peasants in the areas of Mexico mentioned, proceeds from the candelilla harvest were an important part of their income for a long time. Because of continuing improvements in infrastructure, the uneconomical isolation of candelilla wax has decreased since 1950 and been replaced increasingly by agricultural production. Exports to the main consumer, the United States, fell from 2500 t in 1950 [14] to 1800 t in 1974 [33], 1100 t in 1980, and ca. 310 t in 1992 [35]. About 800 – 1000 t of candelilla wax is available on the world market, of which ca. 200 t is consumed in Europe [8].

In the United States, demand for candelilla wax is increasing because of the shift of use from classical areas to those of foods, cosmetics, and pharmaceuticals [35]. Privatization of candelilla wax isolation in Mexico and efforts to produce raffinates there will probably lead to greater availability of these waxes.

2.2.3. Ouricury Wax

Occurrence and Isolation. Ouricury wax is deposited on the leaf stems of feather palms (*Syagros coronata*), which grow mainly in the Brazilian state of Bahia. There it is also known as urucury, licuri, aricuri, nicuri, and coqueiro.

The isolation process for ouricury wax is very similar to that used for carnaúba wax, but it is made more difficult by strong adhesion of the wax to the plant, and mechanical scratching or scraping off is necessary. The annual yield per palm is ca. 1 kg of crude wax.

Preliminary purification involves melting crude wax in hot water and filtering the melt through filter cloths or suitable sieves [12], [14], [36]. Additional purification in filter presses is used to obtain *USA Pure Refined wax.* The crude wax is sold in lumps (Brazilian Crude).

Properties and Composition. Ouricury wax resembles carnaúba wax very closely with regard to its hardness, gloss, solubility in polar and nonpolar solvents, and hardening capacity when used in combination with soft waxes. Its color is somewhat darker than that of dark carnaúba wax types. The *mp* is 82.5 °C. The most important properties for genuine commercial products have been established [20]. Thorough investigation of ouricury wax gave the following composition [37]:

Simple aliphatic esters	23.5 wt %
Monoesters of hydroxycarboxylic acids	22.4 wt %
Diesters of hydroxycarboxylic acids	17.2 wt %
Acidic hydroxypolyesters	5.4 wt %
Free acids	8.7 wt %
Free alcohols	3.0 wt %
Resins	14.8 wt %
Water	1.4 wt %
Ash	0.4 wt %

Alkaline saponification of ouricury wax yields varying quantities of total acids (69 – 74 %) and unsaponifiable components (26 – 31 %), as usual in the case of natural waxes. Despite these facts, ouricury wax, like other vegetable waxes, can be characterized definitely by the chainlength distributions of its *n*-paraffin and acids and alcohol components.

Uses and Importance. Ouricury wax was previously used in floor and shoe polishes and in carbon paper coloring agents, instead of carnaúba wax, mainly because of its low price. As a result of increasing price, the importance of ouricury wax has decreased sharply. According to Brazilian statistics, 39 t was exported in 1980. In 1991 the consumption in the United States was ca. 4.5 t/a [38].

2.2.4. Sugarcane Wax

Occurrence and Isolation. Sugarcane wax is formed as a powdery, pale to dark yellow deposit on sugarcane stalks (particularly in the thickened nodes) in quantities of 0.1 – 0.25 % based on cane weight, depending on country of origin. The main sugarcane-growing countries are India (ca. 96×10^6 t/a), Brazil (ca. 80×10^6 t/a), and Cuba (ca. 40×10^6 t/a).

Sugarcane wax is generally extracted from the dried filter cake (ca. 1 % based on sugarcane) [12] formed during sugarcane processing by using alcohols, carbon disulfide, carbon tetrachloride, or aromatic and aliphatic hydrocarbons [39].

The crude wax content of the filter cake (in weight percent) varies between the following limits, depending on sugarcane origin and method of processing:

India	8.0 – 18.0 wt %
Louisiana	4.4 – 17.9 wt %
Puerto Rico	12.0 – 14.0 wt %
Hawaii	9.6 – 11.0 wt %
Philippines	10.5 – 11.0 wt %
Cuba	12.4 – 22.0 wt %
Java	5.0 – 15.0 wt %
Republic of South Africa	6.9 – 14.6 wt %
Argentina	11.9 – 15.5 wt %
Brazil	8.9 – 17.8 wt %

Crude wax can be freed from most glycerides (fats and oils) by treatment with acetone, methyl ethyl ketone, methanol, ethanol, 1-propanol and isopropanol, 1-butanol, or ethyl acetate. In a subsequent recrystallization step, preferably in isopropanol, resinous and colored components can be removed. Further treatment with bleaching earths or oxidative bleaching of the wax melt with air gives waxes ready for use in a variety of applications. Bleaching processes for prepurified wax using potassium chlorate – sulfuric acid or chromic acid – sulfuric acid would be effective but are not used for cost reasons.

Properties and Composition. *Crude sugarcane wax* is a black-brown to green-brown semisolid with an unpleasant, rancid odor.

Semi- and completely purified products are brown- to yellow-colored hard waxes, whose characteristics vary considerably. Melting points of 68 – 81 °C, acid numbers of 7 – 22 mg KOH/g saponification numbers of 32 – 65 mg KOH/g and proportions of unsaponifiable material of 52 – 62 % have been published in the literature. The following values are typical for a semiraffinate [12]:

Wax esters (aliphatic and sterol esters)	78 – 82 wt %
Free fatty and wax acids	ca. 14 wt %
Free alcohols (wax alcohols and sterols)	6 – 7 wt %
Hydrocarbons	3 – 5 wt %

On comparing crude wax with a raffinate sample [40] in terms of chain-length distributions of the even-numbered acids and wax alcohols and of the paraffins, characteristic differences can be seen, particularly with the acids.

Importance and Uses. From an estimated annual worldwide harvest of ca. 510×10^6 t of sugarcane, ca. 5.1×10^6 t/a of dry filter cake material is theoretically obtained. From this, ca. 510 000 t of crude sugarcane wax could be extracted, given an average wax content of ca. 10 % in the filter cake. If refining losses are assumed to be 50 %, ca. 255 000 t of sugarcane wax raffinate per year remains theoretically available worldwide.

In the past, many attempts have been made to produce crude sugarcane wax on an industrial scale. As early as 1841, isolation of the wax from filter cakes was begun, and in 1909 a corresponding extraction process was patented.

Around 1916, crude sugarcane wax was extracted as a commercial product in South Africa and Java. In 1958 the wax was produced in two Cuban and one Australian plant. However, in 1960, production in Australia was halted and only one plant was still operating in Cuba [39]. In India, an extraction plant is thought to have been operating continuously since 1950 [39]. This plant is attached to a sugar refinery with a daily throughput of 1200 t of sugarcane.

Difficulties resulting from the necessary centralization of production locations, the necessarily rapid and complete drying of large quantities of filter cake material (which has a tendency to ferment), and last, but not least, the increasing costs of extraction have made sugarcane wax raffinate incapable of competing with carnaúba wax on the world market in terms of price. Consequently, sugarcane wax raffinates have only regional importance.

In producer countries, crude sugarcane wax can be used in floor and shoe polishes, carbon paper production, impregnating agents, and production of wax compounds.

2.2.5. Retamo Wax

Occurrence and Isolation. In arid areas of Argentina, *Bulnesia retama* grows wild as trees and shrubs. Branches and twigs are coated with a wax deposit that can be collected mechanically after drying the plant material harvested in summer. The crude wax is purified by melting with dilute sulfuric acid and subsequent filtration through cloths. It is sold exclusively on the home market as retamo wax [12].

Properties and Composition. Retamo wax is a light to medium brown, odorless, hard wax. It is very similar to other vegetable waxes, such as carnaúba wax, with regard to its solubility in polar and nonpolar organic solvents.

Data found in the literature, such as *mp* (76 – 78 °C), acid number (ca. 49 mg KOH/g), saponification number (ca. 87 mg KOH/g), proportion of hydrocarbons (15 – 25 %), and content of unsaponifiable components (38 – 42 %), characterize the wax less precisely than the typical chain-length distributions of even-numbered wax acids and alcohols and of paraffins [40].

Uses and Importance. With a decreasing annual production of several hundred tonnes (1975, ca. 500 t/a), retamo wax is of limited importance on the Argentinian market. It is used for floor, car, and shoe polishes and in the production of colored polishing inks.

2.2.6. Jojoba Oil

According to the DGF definition, jojoba oil is not a wax. However, its chemical composition allows it to be classified as a "liquid wax" in the sense of the classical definition of waxes.

Occurrence and Isolation. The jojoba bush (*Simmondsia chinensis* = *Simmondsia californica* = *Buxus chinensis*) grows wild over an area of ca. 250 000 km^2, most of which lies in the Sonora desert. The population density varies from a few to 500 plants per hectare. In certain areas, millions of jojoba bushes can be found.

The bushes carry fruit capsules that can contain one to three nuts of differing sizes. The yield from the harvest of wild jojoba bushes can range from a few nuts to 14 kg of nuts per plant. The average yield is ca. 1.8 kg per bush.

The nuts contain 50 – 60 wt % oil, which can be extracted almost completely from the deshelled, granulated fruit. Around 35 – 40 % of a particularly high-value oil is obtained by cold pressing and a further 15 – 20 % of a lower-value oil by extraction of the pressed cake. The oil is purified by simple filtration [41].

Properties and Composition. Jojoba oil is a virtually colorless to golden yellow, odorless, unsaturated oil, for which the most important characteristics are as follows:

mp	6.8 – 7.0 °C
Acid number	2 mg KOH/g
Saponification number	92 mg KOH/g
Iodine number	82 g I_2/100 g

A highly crystalline, relatively hard wax is obtained from jojoba oil by hydrogenation. Saponification of the oil gives 51 % unsaponifiable material and 52 % total acid.

Jojoba oil has the following composition with regard to substance groups:

Wax esters	ca. 97.0 wt %
Free alcohols	ca. 1.1 wt %
Free acids	ca. 1.0 wt %
Sterols	ca. 0.9 wt %

Unlike other vegetable waxes, the acids and alcohols in jojoba oil are monounsaturated, straight-chain representatives of the chain-length range $C_{16} - C_{24}$. Among the acids the C_{18} (ca. 12.5 % of the total acids), C_{20} (ca. 67 % of the total), and C_{22} components (ca. 14.5 % of the total) predominate, and among the alcohols, the C_{20} (ca. 48 % of the unsaponifiable components) and C_{22} components (ca. 41 % of the unsaponifiable components). With this unusual composition, jojoba oil is very similar to sperm oil contained in the skull a bone of the sperm whale.

Uses and Importance. An extraordinarily high market demand exists for a sperm oil substitute, which can be satisfied to a great extent by jojoba oil. This demand is a result of the worldwide prohibition of whaling, even though the latter is not obeyed by all countries.

The first experimental jojoba plantations were begun in the United States (Arizona, Texas, and California) to effect infrastructural improvements. Many other jojoba oil plantations were started in Mexico, Argentina, Australia, Brazil, Africa, Egypt, Israel, and countries whose climatic conditions allowed desert farming.

Because management of these plantations is difficult and the time required to achieve economical harvests is relatively long (eight to ten years), jojoba oil is available in insufficient quantities at a very high price. Its use is therefore limited to cosmetics and pharmaceuticals. As soon as reliable quantities can be supplied at

acceptable prices, jojoba oil may attract extraordinarily great interest as a raw material, particularly in the production of high-performance lubricants and in modified form in plasticizers and stabilizers. *Hydrogenated jojoba oil*, which corresponds to fatty esters such as stearyl stearate in its properties, will remain noncompetitive with these esters in terms of price and will therefore not achieve market importance.

2.2.7. Other Vegetable Waxes

Many other vegetable waxes are known, and the composition of some of them has been investigated [12]. However, they are either of very limited local importance or of purely academic interest. These waxes include:

Caranday wax
Raffia wax
Columbia wax
Esparto wax
Alfalfa wax
Bamboo wax
Hemp wax
Douglas fir wax
Cork wax
Sisal wax
Flax wax
Cotton wax
Dammar wax
Cereal wax
Tea wax
Coffee wax
Rice wax
Ocatilla wax
Oleander wax
∗ Palm waxes

Japan tallow wax, which is available commercially, fulfills some application-oriented criteria as a wax but, because of its chemical nature, is a vegetable tallow and thus belongs to the group of other tallows such as myrica, bayberry, ucuhuba, Borneo, Malabar, and illipe.

2.3. Animal Waxes

Animal waxes are obtained mainly from bees (Apoidae), particularly the honeybee (Apidae), stingless bee (Meliponinae), and bumblebee (Bombinae). Some scale insects (Coccidae) also produce waxes.

Waxes obtained from land mammals (sheep, goats, llamas, and dromedaries) and marine animals, as well as those of microbiological origin, are also known.

2.3.1. Beeswax

Beeswax is the oldest natural wax used by humans and still the most important animal wax.

Occurrence. Beeswax is an end product of the metabolism of a honeybee class (*Apis mellifica*, *A. carnica*), which belongs to the *Apis* genus. This species of honeybee is found worldwide and domesticated to a high degree. Wax is secreted from the wax glands in the lowest abdominal segments of the worker bee as white, slightly transparent flakes (virgin wax). From there it is taken to jaw, plasticized by chewing, and then used in this form as a building material for incubating combs and honeycombs.

If plenty of food is available and honey production is increasing, the wax glands are stimulated to enhance production for building new honeycombs. If the beekeeper makes preformed honeycombs available to the bees, honey production is increased [13], [36], [42], [43].

A bee population of ca. 30 000 worker bees produces ca. 270 g of wax from 3 kg of sugar or 3.6 kg of honey in one-fifth of a generation – ca. 50 d. A bee population consumes ca. 50 kg of pollen and 62 kg of honey per year.

Beeswax is produced in almost all countries of the world. In Europe, wax produced in a particular country is consumed there and supplemented by imports. Suppliers are African countries, such as Tunisia, Morocco, Kenya, Tanzania, Zambia, and the Central African Republic. North America, Australia, New Zealand, Russia, and the People's Republic of China also export beeswax.

Isolation. To obtain wax, the combs are freed from honey as far as possible by centrifuging. Then the wax is isolated either thermally by using sunlight or with boiling water. Particularly heavy impurities become enriched in the aqueous phase. Insoluble impurities remaining in the wax melt can be removed by filtration through

a fine mesh sieve of filter cloths, or by pressure filtration or centrifuging.

Colored, wax-soluble impurities can often be removed by treating the wax melt with activated carbon, aluminum or magnesium silicates, or other bleaching earths. As in pressure filtration and centrifugation, wax-containing residues are formed from which lower-quality waxes can be isolated by solvent extraction. The oldest method of lightening the color, which is said to have been practiced in 1000 B.C., involves bleaching beeswax, that has been processed to thin strips or shavings (large surface), in air and sunshine.

In the aforementioned purification processes, beeswax remains chemically unchanged and its characteristic, honeylike odor is retained. The success of the process depends mainly on the source of the beeswax.

Posttreatment of beeswax is now limited to washing with water or adsorptive purification with bleaching or diatomaceous earths. Bleaching with hydrogen peroxide is used out because peroxy compounds are formed [8].

If the process is carried out skillfully, chemical bleaching processes, such as refining with chromic acid – sulfuric acid, give very light, almost chemically unchanged products, which have lost the aromatic odor of the starting material. However, these processes are not employed. The same holds true for those involving mild bleaching with permanganate and sulfuric acid or the use of chlorine-containing bleaching agents such as chlorine bleach, sodium chlorite, and chloramine. The latter give waxes that do not have stable colors and often contain chlorine.

Beeswax is sometimes derivatized by ethoxylation or esterification. The products obtained do not have any market importance.

Properties. Crude, mechanically purified beeswax contains, besides wax, flower and pollen pigments and propolis resin, which acts as a cement in honeycomb construction. Therefore, depending on the source, the wax can have a yellow, orange, or dark brown color.

Beeswax is moderately hard. It becomes plastic and kneadable on warming in the hands, without sticking. It has a noncrystalline, finely grained fracture pattern. On cutting, matt surfaces are produced. Beeswax has a honeylike odor that intensifies on melting. It is moderately soluble in polar and nonpolar organic solvents in the cold, and completely soluble when heated to its boiling point.

Chemically bleached beeswaxes are cream to ivory in color and practically odorless and tasteless. They have a somewhat harder and more brittle consistency than chemically untreated products.

The following limiting values have been established for the properties of mechanically purified and bleached beeswax [20]:

mp	62 – 65 °C
Acid number	17 – 24 mg KOH/g
Ester number	72 – 79 mg KOH/g
Ester number/acid number	3.3 – 4.2
Saponification turbidity point	65 °C

Extensive investigations show that properties vary even among waxes from the same source [44].

Composition. The following values are given in the literature for the approximate composition of beeswax with regard to wax classes:

Wax esters	70 – 80 %
Free acids	10 – 15 %
Paraffins	10 – 20 %

Alkenes, isoparaffins, cholesteryl esters, and pollen pigments are present in minor amounts [12], [45].

Since the typical data for beeswax vary between relatively wide limits, misrepresentation of beeswax is difficult to detect by using these data [46]. A large number of publications exist on the analysis of beeswax [47]. Beeswax can be separated into the various substance classes by chromatographic methods [48–53]. Beeswax of different origin has been shown to have similar composition.

Comparative GC studies, in which ca. 65 % of the waxes investigated are analyzed (residues mostly involatile di- and triesters), also show great similarity among beeswax of widely varying origin [54] (see Table 5).

Parallel GC investigations on a genuine beeswax sample and the same sample after hydrolysis and silylation show that $C_{22} - C_{36}$ wax acids are present predominantly as the free acid, while all $C_{12} - C_{20}$ fatty acids are esterified [54].

Table 5. Composition of beeswax of different origins ∗[54]

Components	Eastern Switzerland	Brazil	China	Canada	Czech Republic
Hydrocarbons, %	14	15	16	14	13
Fatty (wax) acids, %	12	14	9	(8) – 12	13
Fatty alcohols, %	1	1	1	1	
Palmitates, %	22	20	24		
				35 ∗∗	31 ∗∗
Oleates, %	4	3	5		
Hydroxymonoesters, %	12	12	11	(4) – 8	13
Total, %	65	65	66	(62) – 70	70

∗ Values in parantheses were found only in a few cases.
∗∗ Palmitates and oleates.

Gas chromatography of hydrolyzed and silylated beeswax allows a total analysis in which 95 % of its components can be identified [54] (Table 6).

Table 6. Percentages of individual substance classed in a hydrolyzed wax sample from the honeybee *Apis mellifica* (Switzerland) [54]

Chain length (C-number)	Hydrocarbons	Fatty acids	Hydroxy fatty acids	Fatty alcohols
16		17.98	11.60	
17				
18		2.44	0.71	
19				
20		0.15		
21				
22		0.33	1.66	0.12
23	0.25			
24	0.10	4.94	0.59	5.59
25	0.58			
26	0.11	1.75	1.38	3.37
27	4.42			
28	0.08	1.78	0.10	4.37
29	2.64			
30	0.07	1.58		9.58
31	3.27			
32		1.05		7.98
33	2.24			
34		0.94		0.88
35	0.12			
36		0.08		
Total	14.23	33.02	16.04	31.89

Studies using GC show that a spectrum of wax samples from *Apis mellifica* has the same characteristic composition independent of the breed of bee. Small differences exist only in the percentage of individual components and substance classes, so that in general the following ranges of composition are correct for various classes of substance [54]:

Hydrocarbons	13 – 16 %
Fatty acids	30 – 35 %
Palmitic acid	15 – 20 %
Hydroxy fatty acids	13 – 17 %
Fatty alcohols	30 – 35 %
Other substances	4 – 8 %

The remaining substances are present mainly in concentrations of <0.05 %.

By using these facts, beeswax misrepresentation can be detected by a corresponding total analysis of the wax even in the presence of small quantities of blending materials [54].

Uses. Beeswax, mainly the yellow variety, is one of the raw materials used in the production of household *candles*, expensive decorative candles, and candles for religious purposes. For the latter, the Roman Catholic Church prescribes a minimum beeswax content of 10 %. Beeswax is also used for artistic and handicraft purposes (wax flowers, wax sculptures, painting, and batik). Most bleached and purified beeswax is used in *cosmetics and pharmaceuticals* (to regulate the consistency of lipsticks, creams, ointments, and suppositories) and in the *food sector* (as a release agent and a polish in confectionery production). Its use in these areas is favored by corresponding licensing regulations.

A significant proportion of beeswax, ca. 40 % of the total market volume, is sold back to beekeepers for the production of *synthetic honeycombs*, in which blends with paraffins and ceresin, which are not allowed for pharmaceuticals, are often used.

Economic Aspects. From the worldwide honey production figures for 1976, production of 11 000 – 19 000 t of beeswax was esti-

mated. Whether the quantities used in the candle and beekeeping industries were included in the worldwide consumption figure of ca. 10 000 t for 1981, is not known. At that time, total imports for the Federal Republic of Germany amounted to 1000 t.

At present (1994), ca. 15 000 t of beeswax is available on the world market. Ca. 6000 t is used in industry, and ca. 4000 t is sold back to beekeepers [8].

The annual availability of beeswax depends strongly on climatic variations in exporter countries and bee diseases that break out occasionally. In 1993, for example, a marked drop in exports from the United States occurred because of catastrophic weather conditions in the Mississippi area [8].

2.3.2. Other Insect Waxes

The following waxes are not market products and only in some cases have limited regional importance in the countries of origin.

Ghedda Wax. Ghedda wax is produced by some types of wild bee bound in Asia (*Apis indica*, *A. florea, A. dorsata*). It was formerly exported as such but more frequently now is blended with beeswax from the East Indies.

Ghedda wax has a yellow-brown color and varying characteristic data (e.g., acid number 4 – 11 mg KOH/g, saponification number 86 – 130 mg KOH/g, iodine number 5 – 11 g I_2/100 g, *mp* 60 – 66 °C). It has a consistency similar to beeswax with a fatty feel, which can be attributed to its glyceride content. Ghedda wax consists of ca. 78 – 80 % wax esters, 4 % glycerides (fats), 5 – 6 % free acids, 8 – 9 % hydrocarbons, and 1 – 2 % partly resinous impurities [12].

Among the acids are 7- and 16-hydroxypalmitic acids and 7,16-dihydroxymargaric acid, which can be used for identification of ghedda wax or other beeswaxes blended with ghedda wax in modern umpire assays.

Shellac Wax. The resinous exudate of the scale insect *Laccifer lacca* (formerly *Tachardia lacca*) of the Coccidae family is an important commercial product, known as shellac (→ Resins, Natural, Chap. 4.19.). Shellac contains 4 – 5 % wax, which can be obtained by treatment with dilute soda solution or 90 – 95 % ethanol (spirit extraction) as an insoluble component.

Shellac wax is a hard, yellow to brown product. Very light, bleached types are also known. The widely varying data found in the literature (e.g., acid number 12 – 24 mg KOH/g, saponification number 63 – 126 mg KOH/g, iodine number 6 – 9 g I_2/100 g, solidifying point 58 – 80 °C) may be attributed to the different sources of shellac and different methods of extraction and post-treatment of the wax component. Thus, the composition with regard to substance classes also varies as follows [12]:

Wax esters	70 – 82 %
Free acids	10 – 24 %
Free alcohols	< 1 %
Hydrocarbons	1 – 6 %
Shellac	1 – 4 %

Investigations [55] of bleached shellac waxes show that the total acid content of the wax, similar to that of beeswax, consists essentially of a mixture of even-numbered fatty acids ($C_{12} - C_{18}$, 21 – 26 % of the total acid) and waxy acids ($C_{28} - C_{34}$, mainly C_{32} and C_{34}). A significant component is trihydroxypalmitic acid (aleuritic acid), even though it occurs only in quantities of 0.5 – 1.0 %. Among the alcohols ($C_{28} - C_{32}$) the C_{28} component predominates (62 – 65 % of the total alcohol). The main hydrocarbon components are paraffins with 27, 29, and 31 carbon atoms.

Chinese Insect Wax. The East Asian wax scale insect (*Ericerus pela*, subgenus Lecaniinae, family Coccidae) secretes a wax on the twigs and leaves of trees and shrubs on which it is a parasite. The wax can be extracted by melting with hot water. It is hard, brittle, crystalline, and odorless, with a light color, and consists of 95 – 97 % wax esters, 0.5 – 1.0 % free acids, and 2 – 3 % hydrocarbons [12]. The high proportion of wax esters is significant. The East Indian wax scale insect (*Ceroplastes ceriferus*) is said to produce a wax similar to beeswax in composition [12].

2.3.3. Wool Wax

Sheep secrete a substance from their sebaceous glands to protect the epidermis and the wool from adverse weather conditions and from their own acidic perspiration. This substance is incorrectly referred to in the literature as wool fat. Because of its chemical composition it should definitely be classified as a wax.

Wool wax is obtained in emulsified form from raw wool by machine washing with soap liquor. Extraction of wool with suitable organic solvents is not employed because it would lead to complete degreasing of the wool and thus make it nonelastic.

Many processes exist for obtaining crude wool wax from the emulsion, some of them patented [36]. Wax is first precipitated along with the acids of the soap solution by addition of sulfuric acid. The fatty acids remain in the crude product regardless of whether the precipitates are pressed out, centrifuged, or extracted with solvents. They can be removed almost completely by dissolving the crude product (e.g., in hexane) and subsequent extraction with a mixture of alcohol and dilute aqueous sodium hydroxide. Further purification steps (e.g., bleaching with hydrogen peroxide in the presence of phosphoric acid [56]) give neutral wool wax, which is usually treated subsequently with adsorbents such as bleaching earth or activated carbon and sold in a highly pure form as Adeps lanae.

Crude wool wax is a greasy, glutinuous, brown-yellow to brown-black substance with a penetrating goatlike odor (*mp* 34 – 38 °C). *Neutral wool wax* is yellow to light brown in color (*mp* 38 – 42 °C), with a milder odor, whereas *Adeps lanae* is a pale yellow, almost odorless substance (*mp* 40 – 42 °C).

The *composition* of wool wax varies depending on the origin of the wool, breed of sheep, climatic conditions, farming method, and type of pasture.

Wool wax usually consists of a mixture of ca. 48 % wax esters, 33 % sterol esters, 6 % free sterols, 3.5 % free acids, 6 % lactones, and 1 – 2 % hydrocarbons [12]. The low *mp* and appearance of wool wax may be attributed to the high proportion of branched acids.

Uses. Wool wax is used mainly as the crude product, as neutral wool wax, or as hydrogenated neutral wool wax and in the form of wool wax alcohols (obtainable by hydrolysis) in leather polishes, cosmetics (e.g., creams, baby-care products, and toilet soap), pharmaceuticals (e.g., plasters, ointments, and suppositories), and lubricants. The purified, commercial product is known as wool wax or lanolin.

3. Montan Wax

3.1. Formation and Occurrence

Montan wax is a vegetable fossil wax. It forms part of the extractable, bituminous components of lignite and peat. The composition of bitumen depends on the carbonized plant material and on the geology and conditions of the deposit. The main components of bitumen are waxes, resins, asphaltenes, and dark residues. If the proportion of wax is >60 %, the bitumen is generally known as crude montan wax. Prerequisites for formation of this wax were the same or similar to those now necessary for formation of recent natural waxes (e.g., carnaúba wax [57–60]). Lignite, which originates from plant material of the Eocene period, has a high and economically utilizable proportion of wax components. Deposits of lignite, which are used for wax extraction, are found mainly in eastern Germany (Röblingen), Ukraine (Alexandrija), Russia (Baschkiren), the United States (California), and China. Other deposits are of only local importance or are not even exploited. The largest crude montan wax producers are the Montanwerke Romonta in Röblingen (Germany) and the American Lignite Co. in the United States.

3.2. Extraction

The most economically important bitumen-rich lignite deposits are found in the area around the city of Halle in Germany. An industrial process for extracting montan wax from this type of coal was based on investigations bei Riebeck. The original patent [61], [62] for this process, published in 1880, describes how montan wax can be obtained by solvent extraction. In 1900 the production of montan wax was begun in Völpke, and later in other locations. Romonta in Amsdorf

[62] is currently the most important production site. There, lignite with a bitumen content between 10 and 20 % is used for industrial extraction of montan wax. The process used involves the following steps: size reduction, drying, extraction, evaporation of the extract, and formulation [57], [60]. The yield and composition of the extract are determined by coal quality (clay and mineral content); physical parameters such as water content, particle size, and particle-size distribution; and properties of the solvent.

Granulating and Drying. Run-of-mine, pit-wet lignite contains ca. 50 % water. Before extraction it is ground in roll mills and dried to a residual moisture level of ca. 15 % in steam heated tubular dryers. The particle-size distribution is ca. 7 % >8 mm, 75 % 1 – 8 mm, and 18 % fines.

Lignite Extraction and Wax Production. Various machines such as band, chamber, carousel, or bucket chain conveyor extractors are used for extraction. Many solvents and solvent mixtures have been tested and used to extract wax from lignite. They include aliphatic, aromatic, and unsaturated hydrocarbons and hydrocarbon mixtures, mono- and polyhydric alcohols, ketones, esters, ethers, and mixtures of hydrocarbons and alcohols. The yield of extract is highest when polar solvents (e.g., ethanol) or solvent mixtures (e.g., ethanol – toluene) are used. However, the extract then contains a high proportion of polar substances, such as resin acids, sterols, triterpenes, or dark residues, and only a small proportion of wax. With hydrocarbons the overall yield is lower, but the proportion of wax in the extract is significantly higher. In industry, only hydrocarbons or hydrocarbon mixtures are therefore used (e.g., toluene at Romonta in Röblingen). Mixtures of aromatic and aliphatic hydrocarbons and naphthenic benzine are used by other producers.

If toluene is used, extraction is carried out at 85 °C. After extraction, the solvent contains ca. 8 – 10 % dissolved crude montan wax. The mixture is worked up in a three-stage distillation. The bitumen content is increased to 50 % in a continuous evaporator and then to 90 % in a circulation evaporator. The remaining solvent is removed by blowing in steam directly or in a falling-film vaporizer. The wax melt is pelletized or poured into molds. The extracted coal granulates are freed from solvent by steam stripping and used for electricity production in a power station. The toluene – water mixture is worked up, and toluene is recycled to the extraction process.

3.3. Properties and Composition

Crude montan wax is a black-brown, hard, brittle product with a conchoidal fracture pattern. It cannot be scratched by fingernails at room temperature. Crude montan wax has a penetrating terpene-like odor, which becomes very intense on melting. The wax is soluble in many organic solvents, particularly aromatic or chlorinated hydrocarbons, even on moderate heating. Crude montan wax consists of a mixture of wax acids, wax esters, resins, asphaltenes, and dark residues. The ester and acid components can be saponified and emulsified by treatment with aqueous alkali [57], [59], [60]. The waxes form the crystalline component of montan wax. They effect the relatively sharp transition from solid to liquid state and vice versa. The resins and asphaltenes have a more amorphous nature and exhibit glassy behavior. The qualitative and quantitative composition of crude montan wax is determined by the carbonized plants, extent of carbonization, the solvent, and extraction conditions.

A typical crude montan wax contains ca.:

Wax acids	35 %
Wax alcohols	20 %
Hydroxycarboxylic acids	10 %
Dicarboxylic acids	3 %
Wax ketones	1 %
Hydrocarbons	2 %
Resin acids	15 %
Sterols	10 %
Dark residues	4 %

Characteristic properties are:

Acid number	20 – 40 mg KOH/g
Saponification number	70 – 120 mg KOH/g
Iodine number	30 – 45 g I_2/100 g
Drop point	ca. 85 °C
Density (100 °C)	ca. 0.86 g/cm^3
Thermal expansion (20 – 100 °C)	18 %

Wax Components. Crude montan wax contains 70 – 75 % waxlike components, of which the following have been isolated:

Straight-chain carboxylic acids	$C_{16}-C_{34}$
Straight-chain alcohols	$C_{18}-C_{34}$
Straight-chain ω-hydroxycarboxylic acids	$C_{16}-C_{32}$
Straight-chain 2-hydroxycarboxylic acids	$C_{16}-C_{32}$
Straight-chain ω-dicarboxylic acids	$C_{22}-C_{32}$
Esters of $C_{16}-C_{34}$ carboxylic acids and $C_{18}-C_{34}$ alcohols	
Straight-chain aliphatic hydrocarbons	$C_{25}-C_{33}$

These compounds form homologous series, in which chain lengths in the range of $C_{28}-C_{30}$ predominate. The chain-length distribution for straight-chain carboxylic acids and alcohols found by GC analysis is shown in Figure 2.

Resins and Dark Residues. Besides the wax components, crude montan wax also contains ca. 25 – 30 % resins and dark residues. The quantity and composition of these components are determined mainly by the properties of the lignite, the extraction solvent, and the extraction temperature. The resin can be removed from crude montan wax by exhaustive extraction with methanol. In industry, this method is not used to determine resin content because it is expensive and time-consuming. Instead, the proportion of soluble compounds (i.e., resins) is determined by a standardized procedure such as solubility in acetone or in a toluene – ethanol or benzene – ethanol mixture. The resin is characterized by its chemical and physical properties, of which the following are typical:

Drop point	ca. 75 °C
Acid number	ca. 33 mg KOH/g
Saponification number	ca. 75 mg KOH/g
OH number	ca. 70 mg KOH/g
Iodine number	ca. 90 g I_2/100 g
Sulfur content	ca. 2 – 2.5 %

Determination of all individual components in resin extracts has not yet proved possible. However, substance classes and typical compounds in these classes have been identified: e.g., triterpenes such as betulinol, sterols, diterpenoid acids and their esters, and diterpenoid alcohols and their esters.

3.4. Refining and Derivatization

Because of its dark color and its resin content, which sometimes lead to problems, direct use of crude montan wax is limited. For most applications the wax must be refined. Refining involves three steps: extractive deresinification, oxidative bleaching, and subsequent derivatization [57–60], [63].

3.4.1. Deresinification

The resin components of the crude wax are soluble in many solvents even at low temperature (10 – 20 °C). Treatment of pulverized crude wax with methylene chloride, ethyl acetate, or methanol reduces the resin content to 5 – 10 %. Other solvents, such as ketones, ethers, hydrocarbons, mixtures of alcohols and aromatics, liquid SO_2 or supercritical CO_2, can be used but have not achieved industrial importance. After removal of the solvent, the extracted resin contains ca. 10 – 20 % wax. Deresinified wax can be used directly or as a mixture with other wax components for various applications. Such products are sold by Romonta, Amsdorf, and the American Lignite Co. Most deresinified crude wax is subjected to oxidative bleaching.

3.4.2. Bleaching

A purification process for the crude wax was sought very early on. Of the many processes investigated, only three have actually been used in production [57], [60], [64–67].

Distillation was the first method for obtaining light, hard waxes from crude montan wax. The crude wax was heated to 420 °C in stills and thus partially cracked. The distillate therefore consisted of 50 – 80 % hydrocarbons and 20 – 50 % wax acids. The hydrocarbons were removed in a further workup step, leaving the montan wax acids.

Oxidation with Nitric and Sulfuric Acids. In this process, paraffin had to be added as a diluting agent. The resin was precipitated as the nitroresin and removed. The dark residues

Figure 2. Chain-length distribution of acids and alcohols in montan wax

were coked and the wax acids extracted from this coke. However, the wax still had a certain amount of dark residues and nitrate-containing products.

Oxidation with Chromic Acid or Chromates in Sulfuric Acid. In processes described thus far, the wax is damaged considerably and the chainlength distributions of its constituents are altered. Oxidative bleaching with aqueous chromic – sulfuric acid mixtures, developed by I.G. Farben, is much more suitable. The starting material is deresinified crude montan wax. The resin components and dark residues are oxidized to carbon dioxide or low molar mass, water-soluble compounds in a multistage oxidation process. The wax esters are simultaneously hydrolyzed; the wax alcohols formed are oxidized to wax acids; and the hydroxycarboxylic acids are oxidized to dicarboxylic acids. Some esters remain unaltered.

$$CH_3-(CH_2)_n-COO-CH_2-(CH_2)_n-CH_3 \xrightarrow{H_2O} CH_3-(CH_2)_n-COOH + CH_3-(CH_2)_n-CH_2OH$$

$$CH_3-(CH_2)_n-CH_2OH \xrightarrow{CrO_3} CH_3-(CH_2)_n-COOH$$

$$HOCH_2-(CH_2)_n-COO-CH_2-(CH_2)_n-CH_3 \xrightarrow{H_2O} HOCH_2-(CH_2)_n-COOH + CH_3-(CH_2)_n-CH_2OH$$

$$HOCH_2-(CH_2)_n-COOH \xrightarrow{CrO_3} HOOC-(CH_2)_n-COOH$$

where n is an even number between 24 and 32.

A mixture of light wax acids, which are very similar in chain-length distribution to the crude wax, is obtained in a yield of 80 – 85 % based on crude wax. Minor components of the mixture are unchanged esters and long-chain dicarboxylic acids. The spent oxidizing agent is removed and worked up, and the bleached wax is freed from residual chromium salts in a subsequent step.

Depending on the quantity of chromic acid, the acid number of the bleached wax is between 100 and 135 mg KOH/g. Oxidation can be performed batchwise or continuously. In the *Gersthofen process* used by Hoechst, the oxidizing agent is regenerated electrochemically. BASF, Völpke, and other producers use the spent oxidizing agent in an associated plant for the production of chromium-containing tanning agents.

Development is still being carried out on refining processes [68] such as alkaline dehydrogenating oxidation with anhydrous alkali hydroxide. Apparently, these processes have not been used in industry up to now. An overview of the current processes used for extraction and refining of montan wax is given in Figure 3.

3.4.3. Derivatization

Reconstruction of the original wax structure is attempted by treating the wax acids obtained with dihydric alcohols or $Ca(OH)_2$. By varying the proportions of free acid and soap and the degree of esterification, the reaction can be carried out in such a way that the products formed are optimized for a particular application [57], [64], [65], [69].

$$CH_3-(CH_2)_n-COOH + HOCH_2-CH_2OH \rightarrow CH_3-(CH_2)_n-COO-CH_2-CH_2-OR$$

$$R = H \text{ or } CH_3-(CH_2)_n-CO-$$

$$CH_3-(CH_2)_n-COOH + Ca(OH)_2 \rightarrow (CH_3-(CH_2)_n-COO)_2^- Ca^{2+}$$

Figure 3. Flow sheet for extraction and refining of montan waxes

The most important products in this series are the esters of ethylene glycol (e.g., Hoechst Wax E or Hoechst Wax KSL) and mixtures of esters of 1,3-butanediol with calcium montanate (e.g., Hoechst Wax OP). Broad variation in properties can be achieved by using tri- and polyhydric alcohols, aromatic alcohols, aminoalcohols, and ethoxylated or fluorinated alcohols. Reactive waxes can be produced from partial esters of polyols by treatment with dicarboxylic acids, isocyanates, epoxides, or unsaturated carboxylic acids.

R^2 = Alkyl group of the montan wax acid
R = H, R^2CO, R^1

These waxes exhibit interesting properties and have been produced and used for special applications. If the reaction is not stopped at the reactive wax stage and a suitable stoichiometry is chosen, oligomeric waxes are produced.

3.5. Uses and Economic Aspects

Montan wax acid and its derivatives are versatile materials [64] , [65], [69–71]. They are used in the form of flakes, powders, pastes with solvents, or aqueous emulsions. The main areas of use are in polishes for floors, cars, and leather; in plastics processing as lubricants, release agents, and nucleating agents; in the paper and building industries; and in wood and metal processing. Montan wax derivatives are also used in small quantities in pharmaceutical formulations; cosmetics; and the production of adhesives, resins, and office equipment. In addition to their technical properties, the low toxicity of montan wax derivatives and the fact that BGA or FDA approval has already been granted for some derivatives are important criteria favoring their use.

Production figure of montan wax for 1994 are given below, together with a breakdown of montan wax consumption in different application areas:

Crude montan wax	
Romonta	ca. 19 000 t/a
Alpco	ca. 2 500 t/a
Ukraine	ca. 1 500 t/a
China	ca. 1 000 t/a
Bleached montan waxes	
Hoechst Gersthofen	ca. 11 000 t/a
Völpker Montanwachs	ca. 3 500 t/a
China	ca. 500 t/a
Poland	<500 t/a
Czechia	<500 t/a
Application areas	
Plastics, lubricant	ca. 7 000 t/a
Polishes, coatings	ca. 5 500 t/a
Technical applications	ca. 2 500 t/a

4. Petroleum Waxes

4.1. Introduction

The quantity of waxes obtained from crude petroleum has increased continuously for two reasons: (1) the demand for lubricating oils with low pour points and (2) the large proportion of paraffinic crudes in total crude oil production that have to be dewaxed for the production of lubricating oils. This development has increased the need to find more industrial applications for petroleum waxes. When the processing of lubricating oil began in the second half of the 19th century, waxes were still inconvenient side products. Since then, worldwide consumption of petroleum waxes has increased to 3×10^6 t/a. This consumption corresponds to more than 95 % of the waxes of all types produced worldwide. Depending on their natural occurrence and their crystallinity, petroleum waxes are divided into:

1) Macrocrystalline waxes (paraffin waxes)
2) Microcrystalline waxes (microwaxes)

Table 7 gives a detailed classification of paraffin and microcrystalline waxes based on origin and method of refining [80].

Paraffin waxes are obtained from light and middle lubricating oil cuts of vacuum distillation. Paraffin waxes also include waxes from heavy lubricating oil distillates, which are intermediates between macrocrystalline and microcrystalline waxes with regard to structure and composition (*intermediate waxes*).

Microcrystalline waxes originate from vacuum residues and from the sediments of paraffinic crude oil (settling waxes). Waxes that are liquid at room temperature are mostly contained in diesel oil or gas oil fractions (→ Heating Oils, → Aviation Turbine Fuels) and can be isolated from them. These are not dealt with here.

4.2. Macrocrystalline Waxes (Paraffin Waxes)

4.2.1. Chemical Composition and General Properties

Chemical Composition. *Paraffin waxes* consist predominantly of mixtures of straight-chain alkanes in a typical distribution of the homologous series whose molar masses depend on the boiling range of the lubricating oil distillate from which they are obtained. Long-chain, weakly branched isoalkanes are present in a much lower proportion, along with a very small fraction of monocyclic alkanes.

The *intermediate waxes* have a similar composition, but the molar masses of the *n*- and isoalkanes are higher. Intermediate waxes contain a higher proportion of cycloalkanes and isoalkanes; the latter more strongly branched than those in paraffin waxes.

According to the European Wax Federation (EWF), paraffin waxes have a C-number distribution of *n*-alkanes from 18 to 45 and a total content of iso- and cycloalkanes of 0 – 40 %. Typical data for the intermediate waxes are an *n*-alkane C-number of 22 to 60 and a total content of iso- and cycloparaffins of 30 – 60 %.

General Physical Properties. Paraffin waxes are insoluble in water and sparingly soluble in low molar mass aliphatic alcohols and ethers. They are more soluble in ketones,

chlorohydrocarbons, petroleum spirit, solvent naphtha, benzene, toluene, xylene, and higher aromatics, especially at elevated temperature. The solubility decreases markedly with increasing molar mass (higher melting point) of the waxes.

Chemical Properties. Paraffin waxes are extremely unreactive under normal conditions. Oxidation reactions occur only at elevated temperatures (e.g., on storage and processing above 100 °C), particularly in the presence of oxygen and catalytically active metals. These reactions can be recognized from the burnt odor produced and the yellow to brown coloration of the waxes. Nevertheless, under certain thermally and catalytically controlled conditions, these waxes can undergo chemical reactions such as chlorination (→ Chlorinated Hydrocarbons, Chap. 7.3.), oxidation, dehydrogenation, and cracking (→ Oil Refining, Chap. 3.6.3.2., → Oil Refining, Chap. 3.6.4.), of which chlorination and cracking are important in industry.

4.2.2. Division into Product Classes

Depending on the degree of refining, paraffin waxes are divided into the following product classes:

1) Crude waxes, also known as slack waxes
2) Slack wax raffinates (scale waxes)
3) Deoiled slack waxes
4) Soft waxes
5) Semirefined waxes
6) Filtered (decolorized) waxes
7) Fully refined waxes

Table 8 gives an overview of the change in physical characteristics with degree of refining.

Crude waxes (slack waxes) [*64742-61-6*] consist of a mixture of alkanes, which can be solid, semisolid, or liquid at room temperature; alkyl-substituted cyclopentanes and cyclohexanes (naphthenes); and alkyl-substituted aromatics. They also contain, as impurities, the typical contents of the lubricating oil cuts from which they originate, such as asphaltenes, resins, olefins, and sulfur and nitrogen compounds. The oil content of slack waxes is usually between 5 and 12 %, but can be as high as 25 %.

n-Paraffins and isoparaffins predominate in slack waxes in terms of quantity; both are present in continuously distributed homologous series. The chain-length spectrum (C-number distribution) is determined from the width of the boiling range, the distribution maximum (C-number maximum) from the boiling level of the lubricating oil fraction. In isoparaffins, compounds with terminal methyl branches predominate, followed by other methyl-substituted alkanes. The concentration of these compounds decreases as the branching point moves toward the middle of the chain. Other components are compounds with terminal ethyl branches and multiply branched structures, which can be detected only in slack waxes from heavy vacuum distillates [81], [82].

Table 9 shows the composition of some slack waxes as a function of origin.

Physical Properties. Depending on the origin and production process, slack waxes are light- to dark-brown, soft, unctuous to semisolid materials without a clear crystal structure because of their high oil and soft wax content. The congealing points lie between 35 and 65 °C; the drop points, between 35 and 68 °C; the needle penetration at 25 °C (a reciprocal measure of the hardness) is between 40 and 80 (at greater oil content, even higher); the viscosities at 100 °C are between 3 and 10 mm^2/s; the densities at 70 °C, between 775 and 815 kg/m^3; and the flash points between 190 and 250 °C.

Scale Waxes. Normally being physically decolorized slack waxes, scale waxes [*90669-78-6*] essentially have the same composition as the raw materials from which they are obtained. Only the dark material contents of the slack waxes (asphaltenes and resins) are removed by the decolorization process, and the content of alkylaromatics, and of sulfur and nitrogen compounds, is reduced. In physical properties, scale waxes are similar to slack waxes. Decolorization renders the products white to pale yellow.

Deoiled Slack Waxes (Crude Hard Waxes, Raw Waxes). In deoiled slack waxes [*8002-74-2*] the predominant proportion of the hydrocarbons that are liquid (oils) under normal conditions, and a certain proportion of the

semisolid ones (soft waxes), have been removed. Liquid and semisolid waxes consist mainly of low molar mass *n*- and isoparaffins and of isoparaffins with centrally located and strongly branched side chains, as well as naphthenes and alkylaromatics. Therefore, in deoiled slack waxes the *n*- and weakly branched isoparaffins are enriched. By removal of the low molar mass portion a narrower C-number range results along with a more pronounced C-number maximum.

Table 10 shows these relationships with two waxes from heavy spindle oil and medium machine oil used as examples.

Physical Properties. In structure and consistency, deoiled slack waxes are coarse to medium crystalline, brittle to weakly plastic and depending on the degree of deoiling, hard to very hard. These waxes are light to dark brown and darken on heating. The congealing points are between 48 and 72 °C; the drop points between 48 and 75 °C; and the needle penetrations at 25 °C between 10 and 30. At the same degree of deoiling, the course of the penetration – temperature curve (increase in penetration in the penetrogram [83] essentially depends on the origin of the waxes (Fig. 4).

Figure 4. Variation of needle penetration with temperature for deoiled slack waxes of different origins
a) From heavy spindle oil (North Sea); b) From light machine oil (North Sea); c) From heavy machine oil (North Sea); d) Wax from Indonesia

Crude soft waxes [*64742-67-2*] are sometimes known as foot oils (see Section 4.2.3.2) and are formed in the deoiling of slack waxes. They consist predominantly of low molar mass

∗ From heavy spindle oil.
∗∗ From medium machine oil.

n-paraffins and strongly branched isoparaffins; higher molar mass, weakly branched isoparaffins; naphthenes; and alkylaromatics. The *n*-paraffin content of soft waxes is generally <25 wt %.

Soft waxes are very soft, unctuous to inhomogeneous materials at room temperature because of their high oil content, which can be 30 wt % or greater. The oil is included in voids of the crystal lattice of the solid hydrocarbons. Soft waxes have a light- to dark-brown color and congealing points <40 °C. Their viscosities at 100 °C are between 3 and 12 mm^2/s; their flash points, between 180 and 220 °C.

Semi-refined, filtered (decolorized), and fully refined waxes are similar to deoiled slack waxes in the composition of their main components. Through refining they are freed from more highly condensed alkylaromatics and naphthenes, olefins, and sulfur and nitrogen compounds. Depending on the origin, their content of *n*-paraffins varies between 92 wt % (East-Asian waxes) and 45 wt % (waxes from heavy machine oil distillates of German origin). The composition of the refined waxes is determined not only by the origin of the crude (Table 11), but also by the boiling range of the starting distillate. As the boiling ranges of the lubricating oils rise, the molar masses of the hydrocarbons contained in waxes obtained from them increase. The concentration ratio of iso- and cycloparaffins to *n*-paraffins also increases. Thus, for example, a refined wax from Tuismasy (Ural) crudes contains 81.6 % *n*-paraffins with an average molar mass of 360 g/mol (average C-number 25.7) and 9.3 % isoparaffins (average molar mass 384 g/mol; average C-number 27.4). The naphthenes (9.1 %) consist of 81.5 % monocyclic and 15.5 % bicyclic alkanes (average C-number 28.9) [84].

C-number range	23 – 48	23 – 41	25 – 38
C-number max.	34	32	30
C_{max} content, %	10	14	21

Physical Properties. Waxes in this group differ from deoiled slack waxes and from each other in their residual oil content and, thus, in hardness, color, and color stability.

Semirefined waxes have an oil content of 1.5 – 3 %, and the needle penetration at 25 °C can be 20 – 60. They are somewhat plastic and kneadable, colorless to white, have good color stability under light, and are virtually odorless and tasteless.

Filtered (decolorized) waxes have an oil content of 1.5 % (max.) and a needle penetration at 25 °C of 10 – 26. They have a whitish color and are relatively color stable and generally odorless.

Fully refined waxes (oil content and penetration similar to decolorized waxes) are crystalline, no longer kneadable, pure white, transparent to slightly opaque, color stable, light-resistant, odorless, and tasteless. They fulfill purity criteria for the production of packaging materials for foods and for the formulation of cosmetics and pharmaceuticals. Detailed information on the chemical composition of fully refined waxes and methods for their analytical determination can be found in the CONCAWE report [85].

Figure 5. Process schematic for the production of paraffin waxes

According to a more recent definition, fully refined wax products are those that fulfill various national purity requirements (see Section 4.2.5). The oil content, which was once limited to 0.5 % (max.), is no longer a criterion since the oils contained in the wax also consist of *n*- and isoparaffins of the required purity. Depending on the literature, the oil content of fully refined waxes can be 1.5 % (max.) [86] or 2.0 % (max.) [87].

4.2.3. Occurrence of Raw Materials and Processing

Paraffin waxes are contained in crude petroleum and are obtained during oil refining. Depending on the source of the petroleum, the content of solid waxes can vary between 2 % (Rumanian origin) and 30 % (Indonesian origin); generally, however, it is between 3 and 15 % in crude petroleum from the main production areas.

Because of their higher molar masses and thus higher boiling ranges, waxes become enriched in the residues from atmospheric distillation (long residues). In processing the residues to lubricating oils, waxes are obtained in all fractions of the vacuum distillation. Because of their poor solubility, they give rise to the high pour points of the basic oils and must therefore be removed. The yields of wax vary depending on the origin and quality requirements of the oils. For a wax content of crude petroleum of ca. 5 %, 8 – 18 % solid waxes in the individual lubricating oil fractions can be expected.

Slack waxes are produced in the dewaxing of lubricating oil distillates (→ Lubricants and Related Products). The type of process used and process parameters used are according to the desired quality of the lubricating oils.

The process steps necessary for the production of refined waxes are shown in Figure 5.

4.2.3.1. Dewaxing Lubricating Oil Distillates

The principle of dewaxing lubricating oil distillates is based on the different crystallization temperatures of straight-chain and weakly branched paraffins and the oil phase. The wax-containing

Figure 6. Dewaxing of lubricating oil distillates
a) Scraping chiller; b) Cooler; c) Vacuum rotating filter; d) Solvent recovery

solvent-neutral oils (i.e., the raffinates from solvent refining) are mixed with suitable solvents such as propane, naphtha, chlorohydrocarbons, ketones, or (most frequently) a toluene – methyl ethyl ketone mixture. The oil – solvent mixture is subsequently warmed to obtain a homogeneous solution and then cooled continuously in scraping chillers to obtain the wax crystals in a loose suspension. In the subsequent filtration, crystallized wax is separated in vacuum rotary filters, and washed with fresh solvent; the low-wax solvent-neutral oil is then freed from the solvent by distillation. The solvent-containing wax is either separated from the solvent by distillation if it is to be obtained as such or fed directly into the deoiling process for production of hard waxes.

Process conditions are controlled in such a wax that high throughput rates (i.e., short filtration times) and as low an oil content of the slack waxes as possible are achieved [88].

The selectivity of the dewaxing process is controlled by the cooling temperature in the scraping chiller and by the oil – solvent ratio. For common lubricating oil fractions the cooling temperature is between −50 and −20 °C at oil yields of 65 – 85 %. The most important process parameter is the targeted pour point of the dewaxed oil. Figure 6 shows a typical dewaxing process.

In dewaxing, all hydrocarbons with crystallization temperatures above the chosen cooling temperature are removed. *n*-Paraffins are thus almost completely separated, along with a suitable fraction of the long-chain, weakly branched isoparaffins. Even under optimum filtration and washing conditions, impurities consisting of highly branched isoparaffins and cycloparaffins are present in slack waxes, thus giving rise to their oil content [89].

A second process for producing lubricating oils with the required low-temperature properties is *catalytic dewaxing*. *n*-Paraffins are preferentially cracked on zeolite catalysts to give low molar mass hydrocarbons. Wax thus cannot be obtained from this process. Catalytic dewaxing is said to be very selective in the case of heavy distillates, whereas in light distillates the branched paraffins also react (loss of yield). Since no solvents are used in this process it does not require solvent recovery and is therefore environmentally friendly [90].

4.2.3.2. Deoiling Slack Waxes

Refining slack waxes begins with deoiling to obtain harder, higher-value products (hard waxes). The two main processes are solvent and sweat deoiling. The oils produced as byproducts, which contain a higher or lower proportion of soft waxes, are known as foot oils or soft waxes, depending on the consistency and the process used.

Solvent deoiling is the most commonly used process, involving one of three possible techniques: pulping, crystallization, or spray deoiling. Starting materials for all deoiling processes are either molten slack waxes (if deoiling is carried out in a location other than that of slack wax production) or slack wax – solvent mixtures, formed in dewaxing lubricating oil distillates (see Table 12).

Slack waxes from spindle oils to heavy machine oils, and to some extent petroleum as well (see Section 4.3), can be deoiled by the three solvent deoiling methods. The yields of deoiled slack waxes depend on their origin, the process used, and the degree of deoiling. Yields are between 80 % for spindle oil distillates and ca. 60 % for heavy machine oil distillates, based on the slack wax used.

Pulping Process. The inhomogeneous mixture of crystallized wax, oil, and solvent is diluted or repulped by addition of the same solvent or a solvent mixture (normally by using part of the wash filtrates produced later). The oils, soft waxes, and part of the low molar mass hard waxes thus dissolve. The pulp is cooled with stirring in scraping chillers, and the temperature is adjusted to that necessary for the desired degree of deoiling. Hard waxes, which are partly undissolved and have partly recrystallized, are removed on vacuum rotary filters and washed with solvent; the solvent is subsequently distilled off.

The quality of the hard waxes produced is determined by the deoiling temperature and the quantity of solvent used. With a 1,2-dichloroethane – methylene chloride mixture as solvent (Edeleanu Process), for example, typical deoiling temperatures are −10 °C for slack waxes from heavy spindle oil, −5 °C for those from a light machine oil, and +15 °C for those from medium to heavy machine oil.

Crystallization Process. The molten slack wax or solvent-containing wax crystallizate from the dewaxing process is dissolved completely, or almost completely, in solvents by warming, and the mixture is cooled to a given temperature in one or several steps, depending on the desired degree of deoiling. The temperature is chosen such that only the hard wax crystallizes. The crystallizate is filtered and washed, and the solvent is removed by distillation.

In both the pulping and the crystallization processes, technical problems arise in attempting to produce readily filterable hard wax crystals that allow high filtration capacity with good washability. These problems can be solved in various ways: e.g., through the nature and quantity of the solvent; the construction of the crystallization apparatus; successive solvent dosing during cooling; addition of cold solvent to the warm, intensively stirred wax – solvent mixture [91]; and use of filter aids [88]. Other improvements have been brought about by the development of economical cooling and filtration sysems [92].

Spray Deoiling. Molten slack wax is sprayed into a countercurrent of cold air, and precipitated wax particles are washed with solvents in mixers whereby the oil is largely diluted. After settling the washed wax particles are centrifuged and washed, and the adhering solvent is distilled off. The washing temperature is between 5 and 15 °C [93].

Sweat Deoiling. Molten slack wax is charged to chambers equipped with sieve bottoms and heating coils. The wax is solidified by cooling and then warmed very slowly. The oil – and, at higher temperatures, the low-melting soft waxes, as well – sweat from the wax block and run through the perforated bottom (run-off slack wax). At the end of the process the remaining hard wax is melted to remove it from the sweating chamber.

No new plants are being built for this classical deoiling process because of the low selectivity (poor yields of hard wax), time-consuming warmup, need to use a batch process, and inapplicability of the method to strongly oil-binding slack waxes from medium and heavy machine oil distillates. In existing plants an attempt is being made to improve yields of hard waxes by partially recycling the run-off slack [94].

Overview of Processes in Current Use. The deoiling processes most widely used in industry are listed in Table 12.

Of the deoiling plants operating in Germany, half employ solvent deoiling (using mainly the Edeleanu dichloroethane – methylene chloride

Table 12. Processes for deoiling slack waxes [95]

process) and the others use spray deoiling (Edeleanu) and sweat deoiling.

In the United States, more than 90 % of the existing plants use solvent deoiling. The most common solvents are methyl ethyl ketone and methyl ethyl ketone – aromatics mixtures. Propane and methyl isobutyl ketone are also used.

4.2.3.3. Refining Deoiled Slack Waxes

Deoiled slack waxes whose maximum oil content is 0.5 %, 0.5 – 1.5 %, or 2 – 3 %, depending on the use anticipated, still contain impurities and are mostly dark in color. To improve their quality they are purified further by adsorbents (decolorizing) or chemically. The choice of refining process depends on economic factors and the quality of raffinates required. Process combinations have also been introduced into industry. The preferred process in new plants is hydrotreating.

Refining with adsorbents (decolorizing) (→ Lubricants and Related Products) can be performed batchwise, semicontinuously, or continuously. The decolorizing temperature can be between 70 and 120 °C, depending on starting material.

In *batch decolorizing*, molten wax is stirred in heated vessels with decolorizing clays (chemically activated clays, bentonite, bauxite) in one or more steps until the desired lightening of color is achieved. The used clay is removed in heated filter presses and thermally regenerated.

Percolation Process. In the percolation process, molten wax flows downward through a tower containing 10 – 50 t of decolorizing clay, depending on plant size. After the clay has been exhausted, the wax flow is stopped; wax adhering to the clay is washed off with naphtha; the remaining solvent is driven off with steam; and the clay is burnt off in a separate tower, activated, and reused [96].

The *semicontinuous decolorizing process* operates with two or three percolator towers, which are in different phases of the adsorption cycle. While the adsorption process occurs in one tower, in the others the used decolorizing clay is washed, stripped, removed for regeneration, and replaced by new activated clay.

In the *continuous process* the regenerated clay flows downward through the adsorption tower in countercurrent to the molten wax. The loaded clay passes in the form of a sludge to a washing tower where adsorbed wax is extracted with naphtha and then to a second tower where naphtha is driven off wich steam. The clay is then burnt off in a rotary kiln, activated, and fed back to the top of the adsorption tower after cooling [97].

The decolorized waxes are then stripped with steam in packed columns at 110 – 170 °C, either under vacuum (0.6 – 1.6 kPa), under reduced pressure (up to 80 kPa), or under pressure (up to 0.8 MPa) to remove odorous substances. The weight ratio of steam to wax varies between 0.5 : 1 and 1 : 1 at detention times up to 15 min. To improve the aging resistance of the waxes, apparatus with aluminum or stainless steel lining is recommended for stripping [98].

Depending on the starting material, the wax qualities listed in Table 13 are obtained by the decolorizing process.

The quantity of decolorizing clay required depends on the origin and desired quality of

the waxes and is normally between 2 and 4 %. Refining with adsorbents removes dark substances, condensed alkyl aromatics, compounds containing hetero atoms, and metallic impurities.

Nevertheless, producing fully refined waxes fulfilling all of the purity requirements (see Section 4.2.5) by adsorption is possible only using extremely complex processes (multistage decolorizing) and large quantities of decolorizing clay, particularly in the case of the high molar mass wax fractions. To produce these types of high-purity waxes, chemical refining is the process of choice.

Table 13. Wax qualities obtained by decolorization

Starting material	Oil content, %	Decolorized product
Slack wax	>3	scale wax
Deoiled slack wax	1.5 – 3	semirefined wax
Deoiled slack wax	1.5 (max.)	filtered wax [*64742-43-4*]

Chemical Refining. Concentrated sulfuric acid, fuming sulfuric acid (oleum), or hydrogen is used as chemical refining agent.

Sulfuric acid refining can only be carried out batchwise because of the slow separation of the wax and acid sludge phases. Molten wax is mixed with sulfuric acid at 80 – 140 °C for some time (between 0.5 and 2 h, depending on the origin of the wax). After separation of the heavier acid sludge, the wax is washed with alkali, treated with decolorizing clay, and stripped with steam to remove the last residues of impurities and odorous substances.

All compounds that react chemically with the aggressive acid, such as unsaturated aliphatic and aromatic hydrocarbons, metal compounds, and those containing hetero atoms, are removed by sulfuric acid refining. Labile quaternary carbon atoms are also attacked, with bond cleavage and formation of aliphatic sulfonic acids.

The process can be optimized by variation of the number of reaction steps, degree of acidity, reaction temperature, ratio of wax to acid used, reaction time, and intensity of mixing. The higher the average molar mass of the wax fraction, the slower is the separation between the wax and the acid sludge phase.

The process has several disadvantages such as the necessity for batch operations, poor yields of raffinates, formation of polluting byproducts, and waste gas and corrosion problems. For these reasons, almost all new plants are based on hydrotreating.

Hydrotreating (Fig. 7). Deoiled slack wax is heated to the required temperature together with fresh and recycyled hydrogen in the preheater (b) and passed over a sulfur-resistant fixed-bed catalyst (c). After cooling, the reaction mixture and hydrogen are separated in the high-pressure gas separator (d), and hydrogen is recycled into the process. After depressurizing in the low-pressure gas separator (e), the wax passes into the stripper (f), where all the light crack products, odorous substances, and reaction gases are stripped off completely with compressed steam under vacuum. The wax is subsequently dried with nitrogen (g). A combination of metals from groups 6 and 10 on an inert carrier is generally used as the catalyst (e.g., nickel – tungsten or nickel – molybdenum on neutral aluminum oxide).

Reaction conditions can vary within wide limits, depending on starting material, degree of refining required, and composition of the catalyst – e.g., between 200 and 350 °C, 20 and 200 bar, and throughputs of 0.2 – 0.81 L of wax per liter of catalyst and hour. Yields are almost 100 %, based on starting wax [99], [100].

Under the severe reaction conditions of high-pressure hydrogenation, all aromatic compounds are hydrogenated to naphthenes, all dark substances are decomposed, and all sulfur and nitrogen atoms are removed as hydrogen sulfide and ammonia. Metallic impurities become bonded to the catalyst.

The process can be used to refine all classes of wax (paraffin waxes, intermediate waxes, and microwaxes).

4.2.4. Storage, Transportation, Commercial Forms, and Producers

Paraffin waxes are transported in liquid form (molten) in road tank trucks, rail tankers, or liquid containers. Solid waxes are marketed in slabs in small and large cartons and sacks, and as pastilles, flakes, and powder in sacks or big bags. They are also supplied in fiberboard and steel drums and in molded cartons.

Figure 7. Two-step hydrotreating of waxes
a) Deaerator; b) Preheater; c) Reactors; d) High-pressure gas separator; e) Low-pressure gas separator; f) Stripper; g) Vacuum dryer; h) Filter

Even refined waxes can become yellow or decompose to form odorous substances on prolonged heating, particularly in the presence of air or catalytically active metals. On storage, transportation, and processing, the waxes are therefore preferably heated in vessels, fitted with warm water equipment, and the containers and piping are well insulated. Storage tanks are often blanketed with inert gas. In some cases, antioxidants are added to fully refined waxes in quantities up to 0.01 %. Deoiled and refined waxes are differentiated according to melting range (gradation). Some examples of commercial waxes are given below.

Europe	United States
(Melting gradation in °C)	(AMP∗ gradation in °F)
48/50	120 – 122
50/52	122 – 124
52/54	126 – 130
54/56	130 – 132
56/58	132 – 134
58/60	134 – 136
60/62	136 – 140
62/64	143 – 145

∗ AMP = American Paraffin Wax

Important producers of paraffin waxes include: Shell (United Kingdom, United States, Germany), Texaco (United States), BP (France, Germany), Mobil (United States, United Kingdom), Lützendorf (Germany), DEA (Germany), Wintershall (Germany), CFP (France), Total (France), Empetrol (Spain), Petrogal (Portugal). In Germany, for example, the companies either process the waxes to refined waxes (DEA, Wintershall) themselves or sell them to wax refineries (H. O. Schümann). Waxes are *sold* mostly by DEA, H. O. Schümann, and Wintershall.

4.2.5. Quality Specifications and Analysis

The quality specifications of paraffin waxes are determined mainly by their uses. They are differentiated in terms of physical characteristics, chemical composition, purity requirements, and application properties. The following standard specifications have been published for waxes that come in contact with foods:

1) Food and Drug Administration: Code of Federal Regulations (United States) [101]
2) FAO Food and Nutrition Paper (EC) [102]
3) Specifications of the European Wax Federation (EC) [86]
4) Kunststoffe im Lebensmittelverkehr (Plastics which come into contact with foods, Recommendations of the German BGA) [103]
5) Hydrocarbons in Food Regulations (United Kingdom) [104]

For waxes in cosmetic and pharmaceutical preparations, standards are found in the following publications: DAB (Germany), Codes

Français (CF) (France), B.P. (United Kingdom), ISCI Monograph (Japan), U.S. Formulary (United States), and CTFA International Cosmetics Ingredient Dictionary (United States).

The most common test standards for the determination of physical data are summarized in Table 14. The most important test standards for determining chemical composition can be found in Table 15. Some examples of important test methods for determination of the purity of waxes are listed below:

Fluorescence	49th communication of the BGA
Alkali- or acid-reacting substances	DAB, B.P., U.S.P.
Behavior toward sulfuric acid	DAB, BGA, CF, U.S.P.
Presence of polycyclic aromatics	DAB, BGA, FDA

Table 14. Standardized test methods for determination of physical data

[a] XRF = X-ray fluorescence spectromety.
[b] DGF Einheitsmethoden der Deutschen Gesellschaft für Fettwissenschaften [Standardized methods of the Deutsche Gesellschaft für Fettwissenschaften (German Fat association)].
[c] EWF = European Wax Federation.
[d] IP = Institute of Petroleum, United Kingdom.

A looseleaf collection of national and international purity regulations for waxes has been issued by the European Wax Federation and is supplemented continuously [105].

Some of the methods cited are basic test procedures for gaining accreditation according to the series of standards DIN EN 45 000 and the regulations of the Deutsche Akkreditierungsstelle Mineralöl GmbH (DASMIN). With accreditation, DASMIN recognizes the competence of testing laboratories to test the quality of waxes.

The determination of *application properties* is described mostly in in-house methods and includes, for example, oil binding properties, contraction, polishability, abrasion resistance, solvent retention, blocking point, steam permeability, flexibility, extendability, and color stability. Melting and congealing characteristics and latent heats are determined by using differential thermoanalysis [standardized DGF method M-III 14 (1989); ASTM-D 4419-84].

Special analytical methods have been developed to determine the *chemical composition* of paraffin waxes.

The content of *n*- and isoparaffins is determined most accurately by using computer-supported high-temperature gas chromatography [106], [107]. Here, the DGF method M-V9 (1988) is the universal standard. This method allows not only sufficient separation of the *n*- and isoparaffin signals (depending on the column length and injector temperature, waxes up to a C-number of ca. 80 can be determined quantitatively), but also determination of the C-number distribution and position of the C-number maximum.

The determination of *n*- and isoparaffins using urea adduct formation and molecular sieve adsorption has been shown to be a nonquantitative separation method. Only enrichment of the *n*-paraffins results. This, however, clearly diminishes with increasing molar mass and complexity of the waxes investigated [108].

For individual analysis of the different, paraffinic substance groups, coupled GC – MS and GC – NMR methods have been described [85], [109].

The determination of individual polycyclic aromatic hydrocarbons in waxes is currently possible into the μg/kg (ppb) region [85], [110], [111].

4.2.6. Uses

Paraffin waxes are used in very different fields of industry. They not only are used as such, but are also important components of wax compounds (i.e., mixtures of paraffin waxes with other waxes, plastics, resins, etc.). The consumption figures listed in Table 16 cover the most important areas of use.

Slack waxes that are not processed further to refined waxes or subjected to dehydrogenation or cracking processes – for example, to give α-olefins (→ Hydrocarbons, Chap. 2.1.2.1.) – are used mostly in the wood and mineral oil processing industries.

Wood processing requires slack waxes, either molten or in the form of emulsions, mainly for the production of particle board and fiberboard. In the United States the production of artificial logs for barbecues and fires is also important.

In the *mineral oil processing industry*, slack waxes are used to produce petroleum jellies, wire-drawing agents, lubricants, spray emulsions, and anticorrosives.

In addition to wax industry products with a wide area of applications, slack waxes are also used to produce chlorinated paraffins (→ Chlorinated Hydrocarbons, Chap. 7.3.), papers and cardboards for technical uses, cable coverings, solid anticorrosives, fire lighters, and wax torches.

Soft waxes have only a limited market in the production of industrial petroleum jellies and emulsions (wood and building industry), torches, and fire lighters and for conditioning fertilizers. The deoiling of soft waxes gives highly plastic and extendable products (isowaxes).

Refined Waxes [Scale Waxes, Filtered (Decolorized), Semi- and Fully Refined Waxes]. In Germany the producers of candles and wax goods (pictures, sculptures, ornaments) are the main users of refined waxes, which can be processed by all common production methods for candles (molding, drawing, extrusion molding, and powder compressing). In terms of quantity, paraffin wax is the most important raw material for the candle industry.

The second most important consumer of refined waxes is the wax industry, which requires paraffin waxes as an important raw material for compounding wax products for the most widely varying applications.

In the paper, cardboard, and packaging industries, refined waxes are used in the form of emulsions for paper sizing as antifoams in the production of paper, cardboard, and corrugated cardboard; and as impregnating and coating waxes for paper and packaging materials [112].

The viscosity of heat-seal waxes and hot-melt adhesives is adjusted with paraffin waxes. In rubber articles, tires, and solid cable coverings, waxes act as external lubricants/plasticizers, mold-release agents, and rapidly migrating protection agents of rubber against sunlight. They are therefore used predominantly for statically stressed rubber articles (profiles, gaskets, linings, and cable jackets).

Other important applications are in cleansers and polishes (→ Cleansing Agents, Chap. 1.4.; → Shoe Polishes, Chap. 3.1.); cosmetics (creams, ointments, lipsticks); matches; plastics

(external lubricants); office papers; and waterproof textiles (dry impregnation).

In the United States, by far the greatest proportion of refined waxes is used for paper and cardboard finishing, mainly for deep-freeze packaging and wrapping for meat, candy, and flowers; paper cups; yogurt and soft cheese pots; and corrugated cardboard [113].

In the former Soviet Union, refined waxes still play an important role in the production of synthetic fatty acids via catalytic oxidation processes (→ Fatty Acids, Chap. 4.1.). Fatty acids are mainly used in the soap industry.

4.3. Microcrystalline Waxes (Microwaxes)

4.3.1. Chemical Composition and General Properties

Like paraffin waxes, microcrystalline waxes consist of a mixture of saturated hydrocarbons that are predominantly solid at room temperature, such as *n*- and isoalkanes, naphthenes, and alkyl- and naphthene-substituted aromatics. Unlike paraffin waxes, isoparaffins and naphthenic compounds predominate here. The microcrystalline structure can be explained by the presence of strongly branched isoparaffins and naphthenes, which inhibit crystallization.

General Physical Properties. Microcrystalline waxes are insoluble in water and most organic solvents at room temperature. They are moderately to readily soluble in solvents such as chlorohydrocarbons, benzene, toluene, xylene, solvent naphtha, and turpentine oil, especially at elevated temperature. Solubility decreases markedly as molar mass increases. Solvents and oils are retained very strongly by microcrystalline waxes and therefore evaporate very slowly. The quality of some consumer products, such as petroleum jellies or floor and shoe polish, is determined by this retention capacity of microwaxes.

Chemical Properties. Microwaxes are more reactive than paraffin waxes because of the higher concentration of complex branched hydrocarbons with tertiary and quaternary carbon atoms. These C–C bonds are not very thermally stable (i.e. the waxes darken and resinify) on prolonged heating. In addition, they form black tar-like substances on contact with aggressive chemicals such as concentrated sulfuric acid or antimony pentachloride.

The reaction of microwaxes with oxygen at elevated temperature and in the presence of catalytically acting heavy-metal soaps is used for the production of oxidized microwaxes.

4.3.2. Division into Product Classes

Depending on the degree of refining, microwaxes are divided into the following classes:

1) Bright stock slack waxes (petrolatum)
2) Plastic microwaxes
3) Hard microwaxes

Table 17 and Figure 8 show some typical characteristics of microwaxes.

Figure 8. Variation of needle penetration with temperature for various microwaxes compared with a paraffin wax
a) Bright stock slack wax; b) Plastic microwax; c) Hard microwax; d) Paraffin wax 60/62

Bright stock slack waxes (petrolatum) constitute the most complex mixture in the group of microcrystalline waxes. The molar masses of the hydrocarbons can be between 320 and 1200 g/mol. The *n*-alkane content is seldom >10 %. Asphaltenes, hydrocarbon resins, and sulfur, nitrogen, and oxygen compounds are present as impurities. The oil content is normally between 3 and 15 %, but it can be as high as 30 %. Bright stock slack waxes are white

Table 17. Typical physical characteristics of microwaxes

Characteristic	Bright stock slack wax	Plastic microwax		Hard microwax
Congealing point, °C	67	72	75	87
Drop point, °C	76	78	80	91
Needle penetration, 0.1 mm				
at 25 °C	65	30	28	8
at 40 °C	140	85	66	18
Oil content, %	3.8	1.8	1.6	0.4
Viscosity (at 100 °C), mm^2/s	18.7	15.7	14.9	16.2
Refractive index (at 100 °C)	1.4505	1.4458	1.4412	1.4410
Color	dark brown	yellow	white	white

or yellow to dark brown, greasy to softly plastic, unctuous, smooth products with a typical odor, depending on the refining process. They have a very good oil-staining capacity, and some grades have a pronounced stickiness. The congealing points are between 60 and 75 °C; the drop points between 62 and 80 °C; and the hardness (needle penetration at 25 °C), between 45 and 160, depending on the oil content. The viscosities (10 – 30 mm^2/s at 100 °C), densities (810 – 860 kg/m^3 at 80 °C), and flash points (290 – 320 °C) are clearly higher than those of paraffin waxes.

Plastic Microwaxes. In plastic microwaxes the higher molar mass *n*- and isoparaffins and the weakly branched isoparaffins and naphthenes are enriched compared with the petrolatum from which they are obtained by deoiling. Molar masses are between 450 and 1200 g/mol. The *n*-paraffin content can be as high as 40 %. Depending on the degree of refining the impurities present in petrolatum are removed completely or to a great extent. The oil content is usually between 1.5 and 5 %.

The plastic microwaxes, although relatively hard, are definitely plastic, readily moldable, and kneadable. The plasticity is due to the presence of very long carbon chains in the *n*-paraffins and terminally branched isoparaffins. The waxes feel dry to slightly adhesive, and are sold as white to brown products. Congealing points are 65 – 80 °C, and the hardness (needle penetration at 25 °C) is 10 to 60. Highly refined microwaxes are odorless and tasteless.

Hard microwaxes also essentially consist of high molar mass alkanes (predominantly *n*-alkanes and isoalkanes with short side chains statistically distributed over the main carbon chain) and naphthenes. Average molar masses are between ca. 500 and 1200 g/mol. Thus, for example, a refined, hard microwax of North American origin contains 89 % nonpolar hydrocarbons (*n*-, iso-, and cycloparaffins) and has an average C-number of 48 [85]. The *n*-paraffin content can be as high as 70 %.

The extremely microcrystalline to almost amorphous structure of hard microwaxes is associated with the formation of supercooled melts during the setting process.

The waxes are tough and hard, barely ductile and weakly adhesive. Depending on the degree of refining, hard white, yellow and brown microwaxes are on the market, the white to pale yellow products being of highest purity. They solidify between 80 and 94 °C. The needle penetration at 25 °C is <10. The hardness of hard waxes decreases only slightly with temperature until close to their softening point (Fig. 8).

4.3.3. Occurrence of Raw Materials and Processing

Like paraffin waxes, microwaxes are components of crude petroleum. Because of their high molar masses, and thus high boiling range and poor solubility, they either are enriched in the vacuum residues (short residues) from lubricating oil distillation (residual waxes) or separate during the transportation and storage of crude oils (settling waxes). Settling waxes form pasty to solid deposits on the walls of pump tubes and pipelines and on the bottom of storage tanks (pipe and tank bottom waxes). Vacuum residues and pipe and tank bottom waxes are the raw materials for recovery of microcrystalline waxes.

Figure 9. Process schematic for the production of microwaxes

Figure 9 shows schematically the process steps involved in the production of microcrystalline waxes.

In the United States, the most important producer country for microwaxes, the vacuum residues are subjected to deasphalting, refining, and dewaxing to produce high-value bright stock oils. Bright stock slack waxes (petrolatum) are produced in the process as economically important byproducts. However, only in the rarest cases they are processed further to microwaxes in the lube oil refineries themselves. Petrolatum is either marketed directly or used, for example, for the production of petroleum jellies. For further processing it is sold to companies specializing in the production of microwaxes. The same companies also process settling waxes purchased from oil companies.

Deasphalting is the first step in the processing of tank bottom waxes, pipe waxes, and residues, which have been freed from water, mechanical impurities, and volatile components. When propane is used as the deasphalting agent, considerable proportions of resins, polycyclic aromatics, and nitrogen and sulfur compounds are removed. To improve the selectivity with as low a propane throughput as possible, rotating disk contactors are now used instead of packed or sieve bottom columns (→ Lubricants and Related Products). In addition, the extraction process is carried out in two steps [114].

Deasphalting of residues is followed by solvent extraction and dewaxing. The products formed here are the bright stock oils and bright stock slack waxes (petrolatum).

Deoiling. The crude and bright stock slack waxes thus obtained are deoiled by fractional

crystallization (see page 32) if they are to be processed further to microwaxes. Preferred solvents are methyl ethyl ketone and methyl isobutyl ketone, often as a mixture with benzene or toluene. Propane and naphtha, frequently used earlier, have become less important because of their low selectivity.

The crude waxes (deasphalted settling waxes) and bright stock slack waxes are mixed either molten or as a pulp (if the deoiling is to follow immediately after dewaxing the brightstock oils), without isolation of the slack wax with fresh, warm solvents and warmed until only the less soluble (high molar mass) waxes remain undissolved. These waxes are then filtered, washed, and freed from solvent (hard microwax fraction). To obtain plastic microwaxes the filtrate is cooled further. The properties of reprecipitated and refiltered waxes are determined by the filter temperature. The low molar mass, very plastic, and soft microwax foot oils [*64742-67-2*] remains in the filtrate. If the hard microwaxes are not extracted, a one-step crystallization process is sufficient for obtaining plastic microwaxes.

Deoiled microwaxes are still dark yellow to dark brown and not completely odorless, so they must subsequently be refined to satisfy a broad application range.

Refining. Refining is carried out either with adsorbents (decolorizing) or with hydrogen (hydrotreating). Refining with concentrated sulfuric acid, which is possible in principle, has not become important economically because of the high loss of material.

For refining microwaxes with *adsorbents*, the same process principles apply as for decolorizing paraffin wax (see page 33). Since microwaxes are more difficult to decolorize than paraffin waxes, countercurrent percolation is used predominantly. Here, the wax melt continually comes in contact with fresh decolorizing clay [115]. Bauxite is also frequently used as a decolorizing agent.

Hydrotreating is carried out as described for paraffin waxes, in one or two steps in reactors packed with sulfur-resistant, heavy-metal-doped mixed catalysts (see page 34). Reaction conditions are ca. 350 °C and 150 bar, depending on the properties of the catalyst, at a space velocity of 0.3 L of wax per liter of catalyst and hour. Hydrogenated products are treated further by adsorptive decolorizing or stripping to completely remove odorous materials and volatile components.

In the United States, a whole range of microwaxes is produced according to the processed described. Products differ in their congealing point, drop point, hardness, viscosity, and color. They are sold in the liquid (molten) form and as solids in the form of slabs, pellets, and powder.

4.3.4. Commercial Products and Producers

Table 18 shows the most important producers of microwaxes in the United States and the corresponding commercial products.

Table 18. Producers of microwaxes in the United States and commercial products

Producer	Production site	Commercial products
Bareco Div. of Petrolite Corp.	Kilgore, Tex. Barnsdale, Okla.	Petrolite Crown, Be Square, Mekon, Stawax, Cardis, Victory, Ultraflex
Mobil Oil Co.	Beaumont, Tex. Paulsboro, N.J.	Wax Rex, Mobilwax
Quaker State Oil Ref. Corp.	Emlenton, Pa. Farmers Valley, Pa. Newell, W.V.	Microwax, Superflex
Shell Oil Co.	Deer Park, Tex. Wood River, Ill.	Shellwax
Sun Oil Co.	Tulsa, Okla.	Sunoco Wax, Sunolite
Witco Chem. Corp.	Bradford, Pa.	Multiwax

In Europe, H. O. Schümann (Germany), Mobil (United Kingdom), CFR/Total, Mobil, and BP (France), Shell and Witco (Holland), Repsol (Spain), and Petrogal (Portugal), for example, produce microwaxes by deoiling bright stock slack waxes.

4.3.5. Quality Specifications and Analysis

The quality required depends on the industrial use. In principle, the specifications given for paraffin waxes apply here.

Basic product specifications can be found in the following sources:

1) Food and Drug Administration; Code of Federal Regulations (United States) [101]
2) European Wax Federation (EC) [86]

3) Kunststoffe im Lebensmittelverkehr; Empfehlungen des Bundesgesundheitsamtes Deutschland (Plastics for Contact with Foods; Recommendations of the Federal Health Authority, Germany) [103]

The EWF specifies microwaxes for use in packaging materials for foods, as shown in Table 19.

Table 19. Microwaxes for food packaging

Determination	Method	Specification
Congealing point, °C	DIN ISO 2207 ASTM D 938	65 (min.)
Needle penetration, 0.1 mm	DIN 51 579 ASTM D 1321	<50
Extractables, %	ASTM D 721	2.5 (max.)
Viscosity at 100 °C, mm^2/s	DIN 51 562/T1 ASTM D 445	>13
Density at 100 °C, kg/m^3	DIN 51 757 ASTM D 1298	790 – 840
Refractive index at 100 °C	DIN 51 423/T2 ASTM D 1747	1.430 – 1.450
Color	DIN ISO 2049 ASTM D 1500	2.0 (max.)
Odor	ASTM D 1833	weak
Ash content, %	DIN EN 7 ASTM D 482	<0.05
Sulfur content, ppm	DIN 51 400/T7 ASTM D 2622	<300 [a] <4000 [b]
Heavy-metal content (As, Cd, Cr, Pb), ppm	XRF analysis [c]	<1
C-number distribution of *n*-paraffins	DGF M-V9 (88) IP 372-85	23 – 85
Non-*n*-paraffin content, %	DGF M-V9 (88)	25 – 75
UV-Absorption	§ 172.886 FDA	
at 280 – 289 mm		0.15 (max.)
at 290 – 299 mm		0.12 (max.)
at 300 – 359 mm		0.08 (max.)
at 360 – 400 mm		0.02 (max.)

[a] Hydrotreated.
[b] Refined with sulfuric acid/decolorizing clay.
[c] XRF = X-ray fluorescence spectrometry.

In the use of microwaxes to produce food packaging materials, and cheese and chewing gum waxes, purity and physiological nontoxicity are particularly important. For microwaxes the absence of specific polycyclic aromatics is required. These substances can occur as impurities in insufficiently refined waxes, and some of them have been found to be carcinogenic. Polycyclic aromatics can be detected by UV extinction after a special enrichment process (detection limit in microwaxes 10^{-7} g per gram of wax substance). Microwaxes have been shown to be toxicologically and physiologically harmless in extensive animal experiments, when UV adsorption values specified according to test regulations of the FDA [101] and the BGA [103] are not exceeded.

The physical characteristics of microwaxes are determined according to the same standardized methods used for paraffin waxes (see Table 14). In addition, some special analytical methods have been introduced, for example:

Determination of gloss and gloss stability	ASTM D 2895
Determination of blocking point	ASTM D 3234
Determination of sealing stability	TAPPI [Tech. Assoc. Pulp & Paper Ind. (United States)] T 642
Determination of water vapor permeability	ASTM D 988 DIN 53 413
Determination of specific penetration resistance	DIN 53 482
Determination of dielectric loss factor	DIN 53 483

Oil-binding capacity, adhesiveness, and light stability are additional quality factors.

4.3.6. Uses

Bright Stock Slack Waxes. The greatest proportion of bright stock slack waxes is processed further to microwaxes. Important consumers are the wax-producing industry, which requires crude and refined bright stock slack waxes for compounding adhesive waxes, cheese waxes, chewing gum base, cosmetic preparations, sealing and cable compounds, impregnating insulating materials and pesticide sprays; and the mineral oil processing industry, which produces anticorrosives, cavity and underfloor protection agents for motor vehicles, and petroleum jellies. Other uses include the production of artificial fire logs and oxidized petrolatum, which is suitable for the formulation of rust preventives.

Oxidized petrolatum and microwaxes are mainly produced industrially in the United States. Air at normal or at slight overpressure is blown through the wax, which is heated to 150 – 180 °C until the desired degree of oxidation is reached. Darkening of the wax is avoided by adding fresh wax to the reaction zone. Oxidized microwaxes are specified and traded according to their melting range and degree of oxidation (expressed in terms of acid

and saponification numbers). The acid and ester groups, which are distributed statistically over the hydrocarbon chains, can be reacted with inorganic and organic bases to form soaps that can be dispersed in water (emulsified waxes). These compounds also impart to the oxidized waxes an excellent adhesion to metals.

Plastic Microwaxes. The main consumer of plastic microwaxes is the wax industry. Plastic microwaxes are added to wax compounds that require either pronounced plastic or oil- and solvent-staining properties for their industrial applications.

Typical applications include the following:

1) Paper and cardboard coating for packaging meat and sausage products, cereals, bread, candy, ice cream, cookies, yogurt, and frozen food
2) External lubricant (sliding) for extrusion of plastics
3) Formulation of cheese waxes and chewing gum bases
4) Decorative for candles, production of wax pictures and sculptures
5) Polishes and grinding agents
6) Lost wax casting and dental compounds
7) Foam regulators for detergents
8) Protectives against crack formation in tires and rubber articles (sun-proof waxes) [116]
9) Additives for explosives and propellant materials.

Hard microwaxes have numerous applications based on their high melting points and great hardness; favorable hardness – temperature behavior; and good solvent retention. They are used as release agents for pressing plastics and fiberboard, in the production of ceramic articles and in molding polyurethane foam, in solvent-containing cleansing agents, in grinding and polishing pastes, and flat varnishes and paints.

The Committee on Toxicity (COT) in the United Kingdom has recommended that only hard microwaxes be approved for use in the production of cheese waxes, poultry defeathering compounds, and chewing gum [117].

On an industrial scale, hard microwaxes are *oxidized* to an acid number of 30 and are used in this form to produce emulsions (polishes and release agents) and as additives for paints and coatings, printing inks, and office transfer papers.

4.4. Legal Aspects

Apart from environmental effects, petroleum waxes can be absorbed by the human organism via foods (paraffins either are contained in them naturally, have been added to them, or have migrated there from the packaging materials), from chewing gum (only on swallowing or the simultaneous consumption of fat-solubilizing chocolates), and through the use of lipstick. To protect human health, national and international regulations and recommendations have been enacted to limit the oral consumption of waxes.

The use of waxes in packaging materials is subject of *EEC legislation* [118]. In the appendix lists (lists of additives), waxes are permitted, provided that specific migration limits of 0.3 mg per kilogram food for waxes treated with sulfuric acid or decolorizing clay and 3 mg per kilogram for high-pressure hydrotreated waxes are not exceeded.

Extensive literature on the migration of paraffins into foods has been published [119–122].

The permitted paraffins must correspond to published specifications (see Section 4.2.5).

In *Germany* the addition of petroleum waxes to food and animal feed is not allowed. The use of waxes as cheese coatings and in chewing gum is controlled by supplementary regulations.

In the *United Kingdom* the Ministry of Agriculture, Fisheries, and Food (MAFF) proposes a prohibition of petroleum waxes as food additives in England, Scotland, and Northern Ireland [117]. Only specified microwaxes may still be added to foods for a limited period.

In the *United States*, not indication has been given of any intention to ban paraffins in food.

4.5. Ecology

Paraffin and microcrystalline waxes are insoluble in water and can be separated as solids, together with sludge, in oil separators and sewage treatment plants. In the German catalogue of substances that are hazardous to water, they are therefore listed in water hazard class 0 (Wassergefährdungsklasse, WGK 0).

Since paraffins have a water solubility of $< 1\,\mu g/L$, they have no toxic effects on aquatic organisms. Used paraffin-containing packaging materials can be combusted without any problem in waste incineration plants. No polluting substances are formed, and the high calorific value of the paraffins improves the energy balance of the plants.

The *biodegradability* of petroleum waxes satisfies OECD guideline 301 B (1981) [123]. With the exception of microwaxes, biodegradabilities of more than 60 % after 28 d were measured. Bacterial degradation mechanisms are described in [124]. According to this, paraffin-containing packaging materials can also be composted [125–127]. No substances that are toxic or hazardous to groundwater are formed.

The biodegradation of waxes under anaerobic conditions (covered landfills) proceeds much more slowly.

A large number of investigations have been carried out on the *recycling* of used wax-containing packaging materials. The water-insoluble, hydrophobic petroleum wax tends to form particles in the paper mills and give rise to blockages in the sizing equipment [128].

In Europe, ca. 20×10^6 t of waste paper was recycled as a raw material for paper production in 1991. This figure includes 0.35×10^6 t of wax-containing paper and cardboard with average wax content of 12 %. Assuming an even distribution, this gives a wax content of 0.21 % wax in wastepaper [129]. The practice has shown that in modern wastepaper processing plants, wax-containing packaging materials do not interfere with the dilution process,but nearly increase the quantity of waste products. These waste products can be used to produce water-resistant cardbord.

4.6. Economic Aspects

In 1992, 9.5×10^5 t of paraffin and microcrystalline waxes were *produced* in the United States, 8×10^5 t in Asia, 6.5×10^5 t in Western Europe, 2.6×10^5 t in Germany alone, 2.0×10^5 t in Eastern Europe. and 4.0×10^5 t in the rest of the world.

In industrialized countries, a stagnation (probably a decrease) in petroleum wax production is anticipated for the coming years, independent of the growth in demand. This is because of the further development of car engine and tribology technology (reduced specific lubricant consumption and longer periods between oil changes), an increase in the proportion of partially or fully synthetic and biodegradable lubricants, the recycling of used oils, and the closing down of excess capacity in distillation plants despite an increase in the number of motor vehicles and the distances traveled [130].

However, in Asia, particularly China and Malaysia, an increase in wax production to 1.5×10^6 t in 2000 is predicted, because these waxes can be inexpensively produced from indigenous wax-rich crude petroleum by direct dewaxing. According to careful estimates, worldwide petroleum wax production will be ca. 3.8×10^6 t in 2000 (40 % in Asia, 25 % in the United States, 17 % in Western Europe).

The worldwide *consumption* of petroleum waxes was ca. 2.8×10^6 t in 1992, of which (in million tonnes) 0.5 was in Western Europe, 0.2 in Eastern Europe, 0.85 in the United States, and 0.9 in Asia.

4.7. Candles

According to German commercial quality class RAL 040 A2 (Issue 02/1993), candles are sources of heat and light and consist of a wick and a solid combustible material surrounding the wick. Therefore tea lights, lights for graveyards, and oil lamps are also included in this category.

The first candles have been traced to shortly after the birth of Christ. With Christianity, and later with the rise of principalities and the upper middle class, the use of candles developed rapidly. Whereas initially, tow wicks, beeswax, tallow, and spermaceti were used for candle production, from the 19th century onward the use of cotton wicks, petroleum wax, and stearin permitted the problem-free handling of candles.

Today, refined (petroleum) wax is the main raw material used in candle production. Candles are also made from stearin, beeswax, composites (mixtures of various waxes), and ceresin (mixtures of paraffin and hard waxes). Candles are dyed with wax-soluble organic aniline dyes (full dyeing), organic pigments, and (less often) natural pigments (dip dyeing). Fashionable candles with a colored dipping-paint coating are also available. Wicks consist of twisted cotton

threads and are sold as round or flat wicks of different strengths. The wicks are twisted and prepared so as to guarantee uniform burning, good wick curling position, and good suction capacity for the molten combustible material and to prevent afterglow of the wick once the candle has been extinguished. Candles are sometimes perfumed.

A range of mechanical and hand-worked processes exist for industrial production of candles. In the *drawing process* a candle strand is produced by passing the wick several times through the hot wax bath. The strand then passes onto the cutting machine, where it is cut to the desired length of the candle. With continuously operating candle-drawing machines, production of more than 10 000 candles per hour is possible. In the *molding process*, molten wax is poured into molds, in the middle of which the wicks are held taut. Molding machines are available in different sizes. Modern rotating molding machines have an hourly capacity up to 10 000 candles. The *powder pressing process* uses powdered wax as the starting material, which is either molded together with the wick in an extruder to form a candle strand or pressed into molds in a stamp press. At the same time, the wick is introduced with a tubular needle. Another process exists, known as the *dunking process*. Here, the wick is dipped repeatedly into molten wax.

Blank candles are made pointed by using milling cutters and are coated with dyed dip-coating material if necessary.

The quality control of candles involves, for example, determining their weight and dimensions, burning period, and burning properties (no drips or soot). The production of candles in Germany (East and West) was 80 000 t in 1988, and 17 000 t were imported. Thus, with an export of 22 000 t, a total of 75 000 t was consumed within Germany.

5. Fischer – Tropsch Paraffins

Production. The sole producer of Fischer – Tropsch paraffins is South African Coal, Oil and Gas (SASOL) in the Republic of South Africa (→ Coal Liquefaction, Chap. 2.2.). The formerly used ARGE (Ruhrchemie/Lurgi consortium) process, which employed iron catalysts arranged as a fixed bed in multitubular flow reactors, was changed to the SASOL slurry bed proces (SSBP), which afforded considerable cost savings. Production capacity has been doubled [131].

In the slurry or bubble column reactor, finely divided iron catalyst (average particle size 50 µm) is suspended in a Fischer – Tropsch wax with low viscosity at the reaction temperature, and synthesis gas (a mixture of carbon monoxide and hydrogen) is bubbled through. At reaction temperatures of 220 – 240 °C and pressures around 2 MPa, *n*-alkanes and *n*-alkenes are formed preferentially, with up to 40 % crude wax in the synthesis product.

Crude wax is separated from the other products of synthesis by fractional condensation. The low-boiling constituents (gasoline and diesel fuel) are removed by distillation under atmospheric pressure, followed by vacuum distillation to separate the *soft waxes*. Besides *n*-alkanes, distillation bottoms also contain alkenes, hydrocarbons with hydroxyl and carbonyl groups, and colored components. For purification and stabilization, the bottom products are subjected to a hydrofining step employing a nickel catalyst to yield a white *hard wax* that is practically free of alkenes, aromatics, functional hydrocarbons, and sulfur compounds.

Soft waxes are also subjected to hydrogenation.

Properties. Fischer – Tropsch waxes consist essentially of *n*-paraffins with chain lengths between 20 and 50 carbon atoms. Products with an average molar mass of 400 g/mol are marketed as soft, and those with an average molar mass of 700 g/mol as hard waxes. The paraffins have a fine crystalline structure and, because of the narrow molar mass distribution, a small melting range and very low melt viscosities. Congealing point, density, and hardness increase with increasing mean molar mass. The low molar mass compared with polyolefin waxes is the reason for a certain displaceability of the crystal layers relative to each other and, associated with this, the polishability.

Synthetic paraffins are fully compatible with refined waxes, polyolefin waxes, and most vegetable waxes. They are soluble at elevated temperature in the usual wax solvents (e.g., naphtha, turpentine, and toluene) to give clear solutions. Addition of 10 – 20 % synthetic paraffin

to other waxes increases their congealing point and hardness without significantly influencing melt viscosity. In wax pastes, the tendency of Fischer – Tropsch waxes to form microcrystals increases solvent retention. Some typical data for Fischer – Tropsch waxes are listed in Table 20.

Table 20. Typical properties of Fischer – Tropsch soft and hard paraffins

Characteristic	Sasol Wax M	Sasol Wax H2 Vestowax SP 1002
Drop point, °C		106 – 112
Needle penetration, 0.1 mm		1 – 3
Color	white	white
Molar mass, g/mol	400	700
Density (at 23 °C), g/cm^3	0.94	0.94
Viscosity (120 °C), mPa · s	<20	<20

Uses. Fischer – Tropsch waxes are used in plastics processing as lubricants for poly(vinyl chloride) and polystyrene, as well as mold-release agents; as melting point improvers, hardeners, and viscosity reducers in hot melts and candles; and, because of their good polishability, for the production of cleaning agents and polishes.

Micronized waxes improve the abrasion resistance of paints and printing inks.

Oxidized waxes containing fatty acids and fatty acid esters are produced from synthetic paraffin by oxidation and partial saponification. Major areas of application are as mold-release agents in plastics processing, in polishes and cleaning agents, and as auxiliaries in the textile and paper industries.

Trade Names. Fischer – Tropsch waxes are marketed, e.g., as Sasol Wax (Sasol Marketing Co., Johannesburg, South Africa) and Vestowax SH/SP (Hüls AG, Marl, Germany).

6. Polyolefin Waxes

6.1. Production and Properties

6.1.1. Polyethylene Waxes by High-Pressure Polymerization

High-pressure polyethylene (PE) waxes are produced, like high-pressure polyethylene plastic, at high pressure and elevated temperature in the presence of radical formers. As waxes, their molar masses are considerably lower than those of plastics. The molar mass range is adjusted during polymerization by the addition of regulators.

High-pressure polyethylene waxes are partially crystalline and therefore consist mainly of branched molecular chains in which shorter side chains, such as ethyl and butyl, predominate. They generally have low densities (low-density polyethylene waxes, LDPE waxes). Less branched polyethylene waxes with higher crystallinity and density (high-density polyethylene waxes, HDPE waxes) can be produced by increasing the pressure.

High-pressure polyethylene waxes with molar masses between 3000 and 20 000 g/mol [weight-average molar mass $\bar{M}_w$, determined by gel permeation chromatography (GPC)] dominate the market.

The development of high-pressure PE waxes proceeded in parallel to that of LDPE plastics (→ Polyolefins, Chap. 1.1.). In 1939, waxlike ethylene polymers were formed by using a variant of the ICI high-pressure polymerization process [133]. Industrial production of high-pressure ethylene waxes was started in the 1940s [134], [135]. Parallel to this, the technology of thermal depolymerization – the thermal degradation of polyethylene plastics to polyethylene waxes – was developed (see Section 6.1.4).

With the rapid growth of petrochemistry and the expansion of polyethylene plant capacities, the economic importance of PE waxes also increased rapidly. Waxes with very versatile property profiles could be synthesized by varying the density and molar mass of the homopolymers and functionalizing polyethylene by copolymerization with various monomers (e.g., vinyl acetate or acrylic acid) or by melt oxidation.

Because PE waxes are rather inexpensive, have improved applicability and consistency in quality, and are in constant supply they have displaced expensive natural waxes (e.g., carnaúba and montan waxes) in many areas.

The high-pressure process is not applicable for production of polypropylene waxes, because only soft or oily products can be obtained. These waxes are therefore produced by the Ziegler process (see Section 6.1.3) or by depolymerization of high-density polypropylene (see Section 6.1.4).

6.1.1.1. Production

The technology involved in the production of high-pressure PE waxes (see Fig. 10) is analogous to that used for high-pressure polyethylene (→ Polyolefins, Chap. 1.5.1.). The only differences are in the product finishing process. Unlike viscous plastic melts, which must be granulated underwater in granulators, for example, the mobile wax melt can be converted into powder by spraying or into granules by using dicers.

The reaction vessels are stirred autoclaves or tubular reactors (→ Polyolefins, Chap. 1.5.1.1., → Polyolefins, Chap. 1.5.1.2.), the design of which can vary considerably.

Reaction Mechanism. The high-pressure polymerization of ethylene is a highly exothermic radical chain reaction (→ Plastics, General Survey, Chap. 3.3.2.), which is initiated by reaction of ethylene with radicals formed by decomposition of an initiator [136]. Chain propagation occurs through addition of further ethylene units. Chain growth is terminated, for example, by reaction with a regulator molecule such as propene:

$$R-CH_2\dot{C}H_2 + CH_2=CH-CH_3 \rightarrow R-CH{=}CH_2 + CH_3-\dot{C}H-CH_3$$

Polymerization is terminated by recombination or disproportionation of two macroradicals:

$$2\,R-CH_2-\dot{C}H_2 \rightarrow R-CH_2-CH_2-CH_2-CH_2-R$$
$$2\,R-CH_2-\dot{C}H_2 \rightarrow R-CH_2-CH=CH-CH_2-R$$

Long-chain branching occurs by intermolecular chain-transfer reactions:

$$R^1-CH_2\dot{C}H_2 + R^2-CH_2CH_2R^3 \longrightarrow R^1-CH_2CH_3 + R^2-\dot{C}H-CH_2R^3$$
$$\xrightarrow{nCH_2=CH_2} R^2-\underset{\underset{(CH_2CH_2)_{n-1}-CH_2\dot{C}H_2}{|}}{CH}-CH_2R^3$$

A particular feature of polyethylene wax synthesis by the high-pressure process is the increased formation of short ethyl and butyl side chains. These are formed by intramolecular radical transfer:

At the high pressures necessary for polymerization, ethylene is in a supercritical state. Polymerization therefore takes place in a one-phase system. After leaving the reactor, the reaction mixture is decompressed in high- or low-pressure separators, and unreacted ethylene evaporates. The wax remains as a melt and ethylene is recycled.

Reaction Conditions. The structure, molar mass, and thus properties of polyethylene wax are determined mainly by reaction pressure, reaction temperature, type and quantity of initiator and molar mass regulator, and reactor type and geometry [137–141].

In the homo- and copolymerization of ethylene the *reaction pressure* is usually 150 – 320 MPa. Somewhat lower pressures are used in autoclaves than in tubular reactors. Other process variants involve much lower pressures of 70 MPa (max.) with isopropanol as the molar mass regulator [139], [140].

Higher pressure favors chain propagation and thus leads to very short residence times in the reactor. It also inhibits chain-transfer reactions so that with increasing pressure the degree of branching decreases and the density, crystallinity, hardness, and *mp* increase. In tubular reactors, rising pressure increases the polymer yield, whereas in autoclaves this effect is smaller.

For homopolymerizaion the *reaction temperature* is 200 – 350 °C and for copolymerization 200 – 300 °C. High reaction temperature favors chain-transfer reactions. For this reason the polyethylene waxes formed have many short-chain and only a few long-chain branches [142] and thus low densities. Higher-density waxes with lower degrees of branching are formed at lower reaction temperature.

Organic peroxides and molecular oxygen (the latter exclusively in tubular reactors) are used as *initiators*. They decompose into radicals un-

Figure 10. Schematic of production of polyethylene waxes by the high-pressure process in stirred autoclaves
a) Precompressor; b) Postcompressor; c) Autoclave reactor; d) High-pressure separator; e) Low-pressure separator

der polymerization conditions. To ensure that the peroxides are metered reproducibly, they are dissolved in organic solvents.

Hydrogen and almost all organic compounds can act as *molar mass regulators* (chain terminators). Hydrogen, lower alkanes (e.g., propane), lower alkenes (e.g., propene or butene), alkyl aromatics, lower aldehydes (e.g., propionaldehyde), and lower alcohols (e.g., isopropanol) or mixtures of these substances are mainly employed. The concentration and reactivity of these regulators determine the average molar mass, the degree of branching, and thus the density of polyethylene wax. The activity of the regulator increases with increasing temperature and decreases with increasing pressure [136].

Reactor type and geometry also significantly influence polymer structure and properties. Because of the backmixing occurring in *autoclaves*, spherical molecules with many long-chain branches are predominantly formed. In *tubular reactors* with plug flow, long, straight molecules with little long-chain branching predominate [143]. High-density, highly crystalline polyethylene waxes can therefore be produced only in tubular reactors.

Just as the geometries of the autoclave and the tubular reactor differ, so do operating procedures. In the case of autoclaves the initiator solution and the molar mass regulator are charged directly to the preheated pressurized vessel by using high-pressure pumps. In tubular reactors the initiator (e.g., air) and the molar mass regulator are added to the reaction mixture before the compression stage or at the entrance to the reactor. With autoclaves, comonomers can be charged to different parts of the reaction vessel (see Fig. 10).

Product Finishing. Shaping of the molten polyethylene can be performed directly after removal of gaseous products in high- and low-pressure separators and subsequent fine degassing and filtration. Since no metal-containing catalysts are used in high-pressure polymerization of ethylene, no catalyst removal is necessary. Low molar mass fragments and residues of the initiator and molar mass regulator evaporate mainly in the separators. Only an extremely small proportion is incorporated into the polymer.

Granules can be produced by using strip dicers. The wax melt flows in thin strips on a continuous, water-cooled metal band and, after solidification, is chopped with a rotating knife. *Pastilles* can be obtained by metered dripping of

the melt from a distributor head onto this type of cooling band.

A particular characteristic of wax melts is their low melt viscosity. Thus, spraying the melt to form *powders* of spherical particles is also possible. By using special nozzle arrangements (binary nozzles) with nitrogen as the atomizing gas, *micronized waxes* (very fine powders) with particle sizes in the micrometer range can be produced.

Powders and micronized waxes can also be obtained by grinding granules in jet mills. With soft or very viscoelastic waxes, cooling with dry ice or liquid nitrogen is necessary. Coarse particles must be removed by subsequent classification.

Like all organic dusts (e.g., coal or flour), wax powders, and particularly micronized waxes, are highly susceptible to dust explosions. Appropriate safety precautions must be taken during processing, in particular grounding all installations to avoid spark formation through electrostatic charge buildup.

6.1.1.2. Properties

The transition from polyethylene plastic to polyethylene wax is flexible. If the molar mass is lowered, the thermoplastic materials is gradually changed to a wax. The DGF definition of wax (see Section 1.2) gives an approximate boundary: For waxes, an upper limit to the melt viscosity of ca. 20 000 mm^2/s at 120 °C is defined, which corresponds to an average molar mass (weight-average molar mass $\bar{M}_w$) of ca. 37 000 g/mol.

The properties of polyethylene waxes are determined strongly by $\bar{M}_w$ as a measure of the average chain length and by the degree of branching as a measure of the shape of the molecules. Melt viscosity increases with increasing molar mass. Crystallinity, hardness, *mp*, and solidification point increase as the degree of branching decreases. These data are important for application-oriented properties.

The molar mass can be determined by GPC. This method gives the weight-average ($\bar{M}_w$) and the number-average ($\bar{M}_n$) molar mass. The ratio $\bar{M}_w/\bar{M}_n$ is a measure of molar mass distribution and is known as the polydispersity index (→ Polymerization Processes, Chap. 2.1.1.). For high-pressure polyethylene waxes currently produced, this value lies between 2.0 and 2.5. The waxes have a much narrower molar mass distribution than high-pressure polyethylene, for which the values are 3 – 8 (tubular reactor) and 12 – 16 (autoclave) [136].

Table 21 gives a series of structure and property data for three high-pressure polyethylene waxes with increasing density from two different producers (some of this represents unpublished data supplied by the authors).

The following conclusions can be drawn from these data:

1) The degree of branching is generally low with ca. ten branches (max.) per molecule. The side chains are mostly ethyl and butyl groups with a very small proportion of long-chain branches [144–146].
2) The density, crystallinity, hardness, solidification point, and drop point increase as degree of branching decreases [147]. All density-dependent properties vary correspondingly.
3) High-pressure PE waxes contain a small proportion of double bonds, whose distribution in the macromolecule depends on the production process, as the large differences between the levels of central double bonds show. The formation of double bonds is attributed to depolymerization of chain radicals at high reaction temperature [136], [148], e.g.:

High-density polyethylene waxes are colorless, white to transparent and form clear melts. Like other waxes, they dissolve in nonpolar solvents (e.g., aliphatic, aromatic, and chlorinated hydrocarbons) on heating and generally crystallize as very fine particles on cooling. Depending on the type and concentration of the wax, they then form mobile dispersions or paste-like gels, which frequently exhibit thixotropic properties.

6.1.2. Copolymeric Polyethylene Waxes by High-Pressure Polymerization

(→ Polyolefins, Chap. 1.5.1.3.)

In the high-pressure process, many other monomers can copolymerize with ethylene giv-

ing rise to considerable changes in product properties [139], [141]. For copolymerization, autoclaves with their intensive mixing, constant temperature, and consequently stable reaction process are particularly suitable. In industry, vinyl acetate and acrylic acid are used mainly as comonomers, giving waxes with higher polarity and lower crystallinity. Here also, the degree of branching decreases with increasing pressure and decreasing temperature. Density, *mp*, and hardness increase accordingly.

Table 22 gives characteristic data for two important copolymeric high-pressure polyethylene waxes with vinyl acetate and acrylic acid as comonomers.

Table 22. Physical and chemical data for copolymeric high-pressure polyethylene waxes

Characteristic	Ethylene – vinyl acetate copolymer wax	Ethylene – acrylic acid copolymer wax

Vinyl acetate content, %	10	

Ethylene – vinyl acetate copolymer is a relatively polar but nevertheless hydrophobic wax that can be dispersed in organic solvents particularly well. It is used as an additive in metallic automotive paints, as a dispersing agent in pigment concentrates, and as a component of hot melts.

Ethylene – acrylic acid copolymer is suitable for aqueous systems because it can be emulsified readily and is chemically and thermally intensive. Its emulsions are used mainly in modern floor polishes and mold-release agents.

6.1.3. Polyolefin Waxes by Ziegler – Natta Polymerization

Like high molar mass polyethylene plastics, PE waxes can be produced by the Ziegler low-pressure process using organometallic catalysts (→ Polyolefins, Chap. 1.5.2.), in addition to the radical process at high pressure and temperature. Like high-density polyethylene, Ziegler waxes have a mainly linear molecular structure. They can contain short side chains but not long ones like high-pressure polyethylene waxes.

For direct synthesis of polymer waxes from propylene or higher α-olefins, only the Ziegler – Natta process is suitable (→ Polyolefins, Chap. 2.5.).

Ziegler PE waxes currently on the market have a molar mass between 800 and 8000 g/mol ($\bar{M}_n$). They thus bridge the gap between Fischer – Tropsch and paraffin waxes and HDPE thermoplastics. Besides controlling chain length, the polymerization process allows adjustment of the degree of crystallinity so that both hard – brittle, high-melting products and

softer, flexible products with low melting points can be obtained.

The soluble, soft wax fractions inevitably produced in the suspension process for HDPE are more similar to paraffin waxes than to PE waxes because of their low molar masses. For normal hard wax applications, they can be used only after processing by distillation or extraction [149].

6.1.3.1. Production

For the production of Ziegler – Natta polyolefin waxes, Ziegler catalysts that give polymers with low average chain lengths and narrow chain-length distributions, and are sufficiently active under the special conditions of wax synthesis, are particularly suitable. The low degree of polymerization typical of waxes is achieved by carrying out polymerization in the presence of hydrogen as a molar mass regulator at comparatively high temperature (usually between 100 and 200 °C, sometimes even higher) [150–154]. Aliphatic hydrocarbons are used as reaction medium. Because of the high reaction temperature the waxes are formed in solution (solution polymerization). If the product viscosity is sufficiently low the molten polymer formed can itself function as the solvent (bulk polymerization) [155], [156]. Unlike modern HDPE processes in which the catalyst is not removed, in the case of wax synthesis the catalyst must usually be decomposed and filtered off [157], [158]. This applies at least to the heterogeneous titanium catalysts still used today (see below) and is necessary because waxes have higher purity requirements than PE plastics as a consequence of the applications for which they are used. After the solvent has been distilled off, the wax melt is shaped (e.g., by spraying or pastille formation).

Catalyst Systems. Classical Ziegler catalysts, consisting of titanium tetrachloride and alkylaluminum compounds, can be used for wax synthesis, but their activity is low [155], [156], [159–161]. The degree of branching and thus also the density, drop point, and hardness can be adjusted by copolymerization, by the special type of catalyst preparation [160], and by varying the polymerization temperature [155], [161].

The state of the art for production of *PE homo- and copolymer waxes* involves, as in plastics production, the use of supported catalysts, which contain titanium atoms as the active species and magnesium compounds as the carrier material (→ Polyolefins, Chap. 1.3.2.2.). Catalysts derived from titanium tetrachloride and magnesium chloride, oxide, hydroxide [151–154], or alkoxide [150], for example, are suitable.

Catalysts based on Ti – Mg compounds can also be used in the production of *polypropylene waxes.* Through an appropriate choice of catalyst, the degree of crystallinity (isotacticity) (→ Polyolefins, Chap. 2.2.) can be varied within wide limits and thus adapted to a particular application. Flexible products with average crystallinity can be obtained [162]. Highly crystalline polypropylene waxes can now be produced economically by using stereoregulating silanes as additional catalyst components [163], [164]. Formerly, these waxes could be produced only by thermal degradation of high molar mass polypropylene (Section 6.1.4).

Indications are that the homogeneous metallocene – alumoxane catalyst systems [165], [166], which became known at the end of the 1970s and nowadays are used for plastics synthesis in industry, will also become important in wax synthesis. Since the 1980s, many patent applications have appeared in this field, relating to both PE [167–172] and PP [173–175] waxes. Metallocene catalysts have a number of advantages compared with titanium catalysts. They are more active and can thus be employed in lower quantities, so catalyst removal is not necessary. Polymerization can occur at lower temperature, and the process is therefore more economical. Above all, the specific polymerization properties and great structural variability of metallocene systems are likely to give polyolefin waxes with optimized or completely new property profiles.

6.1.3.2. Properties

The most important molecular structure parameters, which determine the macroscopic property profile of PE waxes, are the average molar mass (average chain length) and the degree of branching. Melt viscosity rises exponentially with in-

creasing molar mass (Fig. 11). Unbranched, *homopolymeric PE waxes* have a high degree of crystallinity as a result of their undistorted linear molecular structure. They are brittle and hard (needle penetration numbers <1) and have high densities and melting points (up to ca. 127 °C). These products can be obtained only by Ziegler polymerization. Radical polymerization always gives branched waxes.

Figure 11. Relationship between average molar mass $\bar{M}_w$ and melt viscosity for PE waxes

By using *1-alkenes* (generally propene) *as copolymers*, defects can be introduced into the polymer chain in the form of short-chain branches, which lead to a decrease in crystallinity. The density, hardness, drop point, and heat of fusion are also decreased, while flexibility and plasticity increase.

In Table 23, some important physical properties of typical commercially available Ziegler polyolefin waxes are compared.

Ziegler waxes are colorless and odorless and form clear, transparent melts with high thermostability. Like most other waxes, they are soluble on warming in nonpolar aliphatic and aromatic solvents without leaving a residue, and on cooling often crystallize out as pastes. Commercial products have a melt viscosity range from ca. 10 to 30 000 mPa · s (at 140 °C). Their densities are between 0.92 and 0.97 g/cm^3.

6.1.4. Degradation Polyolefin Waxes

By heating in the absence of air, the molecular chain of high molar mass polyolefins can be cleaved into smaller molecules with wax-like character. The starting materials are usually low- and high-density polyethylene, isotactic polypropylene, and polybutene. The production capacities of degradation polyolefin waxes have diminished since ca. 1980 in favor of the built products (see Sections 6.1.1, 6.1.2, 6.1.3). While the proportion of degradation PE waxes has diminished, that of PP waxes has increased. Despite the relatively unfavorable energy balance of the degradation process, it is still used because of its technological simplicity and, for PE waxes, occupies third place with regard to the production quantity after the high-pressure and low-pressure PE waxes. The degradation process was developed approximately in parallel to high-pressure polymerization [176–178].

6.1.4.1. Production

Polyethylene is a thermally stable polymeric hydrocarbon. In the absence of oxyen it can withstand temperatures up to ca. 290 °C [179]. At higher temperature, thermal degradation begins with a decrease in the molar mass; from 400 °C, degradation occurs with high rate and yield [179]. The cleavage products consist almost exclusively of a wax fraction with a molar mass distribution that is barely wider than that of high-pressure PE waxes. Low-boiling and gaseous crack products are formed only in small quantities. Individual process steps are shown in Figure 12.

Figure 12. Process schematic for the production of degradation polyolefin waxes

Table 23. Structure and properties of typical commercial Ziegler polyolefin waxes

	A Ethylene homopolymer wax	B Ethylene copolymer wax	C Ethylene homopolymer wax	D Ethylene homopolymer wax	E Propylene homopolymer wax

The starting materials for thermal degradation to polyolefin waxes are LDPE and HDPE [180] and HD polypropylene [181–184]. Degradation of copolymeric polyolefins [185] and polybutenes [186] has also been described but has not achieved great economic importance.

In the industrial process [180], polyolefin pellets are melted under nitrogen in a single-screw extruder and extruded into a steel tube heated to ca. 400 °C. The residence time is 15 – 30 min. The product is then cooled by evaporative cooling in ca. 5 min to <250 °C. It is freed from low molar mass components by degassing in a separator. The product can then be finished as described for high-pressure PE wax (Section 6.1.4.1).

The degree of branching of degradation waxes formed, and thus all structure-dependent properties such as crystallinity, density, hardness, and *mp*, are controlled by the choice of starting material (LDPE or HDPE, stabilizer free). The average molar mass depends on residence time in the hot-tube reactor and the average molar mass of the starting material. The degradation temperature affects mainly the reaction time and thus the throughput rate.

Batchwise, thermal degradation in autoclaves has also been described [182], [185]. It is performed in certain cases in the presence of hydrogen and hydrogenation catalysts to saturate double bonds formed on chain cleavage [176].

Like other polyethylene waxes, degradation waxes can be modified by air oxidation and thus rendered emulsifiable (see Section 6.1.5). Preliminary hydrogenation of double bonds can be necessary to avoid cross-linking reactions during oxidation.

Because of their double bonds, degradation waxes are particularly suited to grafting with unsaturated carboxylic acids (e.g., with maleic anhydride [187], [188]).

Little information is available in the literature on the mechanism of thermal degradation of polyolefins to form waxes [179]. Presumably, radicals form from the few oxygen-containing groups in the polyolefin and initiate a radical chain reaction, in which the chain is cleaved through radical transfer and a double bond is formed:

Since tertiary hydrogen atoms are particularly susceptible to radical transfer, the degradation reaction begins at the carbon atoms of the branches, to form fragments containing side-

chain double bonds. Only later are linear chains cleaved, to form central and terminal double bonds.

6.1.4.2. Properties

In Table 24, properties (in some cases unpublished results supplied by the authors) of three degradation and three high-pressure polyethylene waxes, with about the same average molar mass to decreasing branching and increasing density, are compared. The two types of wax can be seen not to differ significantly. For both, the same relationships are valid between molar mass and melt viscosity and between degree of branching and density, crystallinity, hardness, and solidification and drop points. The width of the average molar mass distribution (polydispersity) is also comparable. A significant difference is that degradation polyethylene waxes contain considerably more double bonds than comparable polyethylene waxes formed by high-pressure polymerization. Determination of the type and level of double bonds from the IR spectrum can therefore be used for analytical identification of degradation polyethylene waxes. The technical properties are affected only slightly by double bonds.

Compared with degradation polyethylene waxes, *degradation polypropylene waxes* usually have extremely high melting points and hardness because they are produced from highly crystalline, isotactic high-density polypropylene. Some characteristics of a relatively low molar mass degradation polypropylene wax are listed below:

mp (DSC)	130 – 160 °C
Ball indentation hardness (23 °C) (DGF-M-III 9a)	500 – 1900 bar
Melt viscosity (200 °C) (DGF-M-III 8)	800 – 1900 m^2/s
Weight-average molar mass (GPC, standard: PP)	17 000 – 37 000 g/mol

Degradation polyolefin waxes are colorless, white to transparent, and form clear melts. On warming, they dissolve in nonpolar solvents such as aliphatic, aromatic, and chlorinated hydrocarbons, and on cooling, they crystallize as dispersions or gels (pastes).

6.1.5. Polar Polyolefin Waxes

Polar polyolefin waxes generally contain carboxyl and ester groups, which give them special technical properties, in particular emulsifiability in aqueous media. They can be produced by a variety of methods:

1) Oxidation of nonpolar PE waxes (melt oxidation) or PE plastics (oxidative degradation) with air
2) Radical high-pressure polymerization of ethylene with oxygen-containing comonomers (acrylic acid, acrylates, vinyl acetate, etc.) (see Section 6.1.1.1)
3) Radical grafting of polar unsaturated monomers onto nonpolar PE and PP waxes

To a great extent, PE waxes are converted into wax oxidates by treatment with atmospheric oxygen in the melt at ca. 150 – 160 °C [189–191]. Oxygen functions (carboxyl, ester, carbonyl, hydroxyl groups, etc.) are introduced into the wax molecule by complex mechanisms involving peroxy intermediates and chain-shortening reactions [192]. The usual commercial products with acid numbers between 25 and 30 mg of KOH per gram contain ca. 3 – 4 wt % oxygen, mainly in the form of carboxyl and ester groups.

Oxidation of the molten wax is limited to waxes whose molar mass is not too high. In the case of longer-chain starting materials, intensive dispersion of air in the melt, which is necessary for the reaction to run smoothly, is inhibited by the melt's high viscosity. In this case, waxes can be oxidized in *inert dispersion agents*. Since a (statistical) chain cleavage is always associated with oxidation (i.e., a lowering of molar mass), PE plastics can also be converted into a polar wax by this route (*oxidative degradation*). For example, molten polyethylene in an aqueous dispersion can be converted into emulsifiable waxes by passing in air at 130 – 160 °C with intensive stirring. These waxes are harder and have higher drop points than the usual melt oxidates with the same acid number because of their relatively high molar masses [193]. The reaction can be accelerated by addition of peroxides. High-density polyethylene gives hard brittle products. Tough, flexible waxes, which can be used as antislip components of floor polishes, can be obtained from LDPE containing vinyl acetate [194].

Oxidative degradation of polyethylene can also be carried out as a *gas – solid reaction*. In this case, no dispersing agent is required. Air, oxygen-enriched air, or pure oxygen in the presence of radical initiators is reacted with the substrate in powder form a few degrees below the softening point [195–198]. Because a low temperature (<130 °C) must be maintained, the oxidation period is comparatively long. For example, it requires at least 20 h to achieve acid numbers of 25 – 30 mg of KOH per gram. Use of air – ozone mixtures as the oxidizing agent has also been described [199], [200]. Another process variant involves oxidation of polyethylene powder with air in *aqueous suspension* under pressure [201]. The properties of some representative commercial wax and plastic oxidates are given in Table 25.

Oxidized PE waxes can be modified further by esterification [202], amidation [203–205], saponification, and other derivatization reactions [206] and thus adapted to special technical requirements.

Polyolefin waxes can also be converted into emulsifiable products by *grafting unsaturated polar compounds* (maleic anhydride, etc.) [161], [207–210]. For *polypropylene wax* [211–213], this is the only method of introducing oxygen functions that is used in practice, since air oxidation would lead to low molar mass, colored, soft degradation products.

6.2. Uses

6.2.1. Nonpolar Polyolefin Waxes

Polyolefin waxes are used in widely differing applications, mostly as auxiliaries in products and production processes. The areas of use of high-pressure, Ziegler, and degradation waxes overlap extensively. More details can be found

in leaflets and brochures of various production companies. Important areas of use include the following:

1) *In Additive and Pigment Master batches.* PE and PP waxes are carrier materials and binders in concentrates used as plastics additive and for coloration of plastics.
2) *As Additives to Improve Rub Resistance and as Slip Agents* [214]. PE waxes are incorporated into printing inks after micronizing by milling or spraying, or in the form of dispersions.
3) *In Paints and Coatings*, PE waxes are used for matting effects and to increase resistance to scratching [215], [216].
4) *In Plastics Processing*, PE waxes are used as lubricants and release agents in molding.
5) *In Polishes*. PE waxes are components of heat-resistant pastes for floor, shoe, and car polishes.
6) *In Hotmelt Coatings.* PE and PP waxes are heat-sealable components of coatings and adhesives for paper and metal sheeting because they improve insulation, gloss properties) and heat resistance.
7) *For Corrosion Protection*. PE waxes are used as hydrophobing components for temporary corrosion protection of motor vehicles, machines, and instruments.
8) *Photocopying.* PE and highly crystalline PP waxes are used in toner preparations for photocopying machines.
9) *In the Rubber Industry*, PE waxes are used as release agents in processing.

Also, PE and PP waxes are used as components of insulating compounds, as carriers and binders for mechanically and chemically reacting self-duplicating paper and wax crayons, to coat granular fertilizer, and to increase the heat resistance of candles.

6.2.2. Polar Polyolefin Waxes

Polar polyolefin waxes are used mainly in the form of aqueous emulsions (dispersions). Depending on the nature of the emulsifier system used, nonionic, nonionic – ionic, anionic, and cationic formulations can be produced. Emulsions are produced by mixing molten waxes and emulsifiers with hot water. On rapid cooling with intensive stirring, wax droplets solidify and form stable, finely divided dispersions. High-melting waxes must be emulsified under pressure. After the emulsion is applied, water evaporates and leaves a homogeneous wax film, often with a high gloss, on the treated surface. This effect is used in floor polishes where polar waxes are applied in combination with acrylate- and styrene-based polymer dispersions. Waxes obtained by oxidative degradation of plastics are primarily used in this area because they form harder-wearing films due to their greater hardness than lower molar mass melt oxidates. Polyethylene wax emulsions are also used as leather and shoe polishes and in many other areas of industry. In textiles, they are used for wash and wear finishes and to improve sewing properties. They are used as hydrophobing agents in paint dispersions, as release agents in the building industry, and in surface finishing of paper products. Citrus fruit is provided with a glossy surface and protected from drying out through the application of wax films [217]. In the plastics processing industry, polar PE waxes are used as lubricants and release agents.

6.3. Economic Importance

As indispensable additives with a secure raw material supply and broad application potential, polyolefin waxes play an important role, mainly in the industrial, but also in the consumer market sectors.

The quantity of polyolefin waxes annually consumed worldwide is ca. 200 000 t (1995), including oxidized and grafted products. High-pressure waxes (PE and polar copolymers) account for ca. 70 %. The remainder consists essentially of Ziegler products (PE, PP). Degradation waxes (mainly PP) are less important in terms of quantity.

Ca. 12 000 t of polar waxes are produced worldwide by oxidative degradation of PE plastics.

The main consumers of nonpolar polyolefin waxes are the producers of pigment concentrates and of plastic and rubber articles, as well as the paint and printing ink industry. Polar waxes are used mainly in the form of emulsions in the textile, polish, and paper industries.

Producers and Trade Names.

High-Pressure Waxes. Allied-Signal, United States (A-C Polyethylene). Eastman Kodak, United States (Epolene Wax). BASF, Germany (Polyethylenwachs BASF, Luwax). Leuna, Germany (LE-Wachs).

Ziegler Waxes. Hoechst, Germany (Hoechst-Wachs). Mitsui Petrochemical Ind., Japan (Hiwax). Hüls, Germany (Vestowax). Petrolite, United States (Polywax).

Degradation Waxes. Sanyo Chemical Industries, Japan (Viscol, Youmex). Mitsui Petrochemical Ind., Japan (NP-Types). Lion Chemical, Korea (L-C Wax). Eastman Kodak, United States (Epolene). Ceralit, Brazil (Cerit Poly).

7. Toxicology

On the basis of experience accumulated over thousands of years, waxes are generally considered harmless, nontoxic, environmentally friendly products. The results of scientific toxicological and ecotoxicological tests on natural waxes, montan waxes, polyethylene waxes, and other wax products generally support this.

Natural Waxes. From the group of animal and vegetable waxes, *carnaúba wax* was subjected to toxicological tests. In a two-generation feeding experiment, 1 % wax (max.) based on the feed, was administered first to pregnant rats and then to their first-generation offspring over a period of 90 d. The results gave no indication of dose-dependent effects in the rats treated compared to the untreated control group [218].

Montan Waxes and Their Derivatives. The toxicological properties of acid, ester, and partially saponified ester waxes (partially neutralized with calcium hydroxide) derived from montan wax are determined mainly by the indigestibility of the products, as in the case of natural waxes. Besides determining acute oral toxicity, extensive feeding experiments on rats and dogs over periods of 90 d, 140 d, and 2 a have been carried out with montan wax derivatives [219]. The LD_{50} values are >15 000 and 20 000 mg per kilogram of body weight, respectively. According to the usual classification, these products are considered practically nontoxic and harmless [220].

Long-term feeding experiments led to no macroscopically or microscopically recognizable toxicological damage to the animals, even at very high dosages of 5 % in the feed (Table 26).

Dermatological examination of montan wax derivatives in the percutaneous test and the mucous membrane test on rabbits (Hoechst waxes S, E, and OP) did not lead to any irritation of the skin or mucous membranes.

In the Ames mutagenicity test with and without external metabolic activation, a montanic acid – ethylene glycol ester wax (Hoechst wax E) did not show any mutagenicity (tested dosages 4 – 5000 µg per plate) [221].

The *ecotoxicological behavior* of montan waxes is attributed to their water insolubility. Mixtures with water are attacked very slowly by microorganisms and cause no perceptible biological oxygen demand (BOD) in water bodies and sewage treatment plants. The waxes are separated from wastewater as ballast materials together with sludge. In the determination of biodegradability according to OECD test method 302 B (static test/Zahn – Wellens test), the finely dispersed montan wax derivatives in wastewater show good elimination of chemical oxygen demand (→ Ecology and Exotoxicology). They are separated with sludge and are nontoxic to fish and bacteria.

In the case of wax emulsions, when the usual test methods for determination of COD and BOD are used, a very slow oxygen consumption can be detected, which is higher than the oxygen demand of the emulsifiers [219]. In wastewater, these emulsions break up as a result of great dilution, altered pH, and the presence of calcium and magnesium ions. The findings described for pure wax – water mixtures also apply to the agglomerates formed.

Polyolefin Waxes. Polyethylene waxes, oxidized polyethylene waxes, and polypropylene waxes are similar to those based on montan wax and natural waxes with regard to toxicology. The LD_{50} values for rats are >5000 and 15 000 mg per kilogram of body weight, respectively. In a long-term toxicity test (a 9-month feeding experiment on rats), polyethylene waxes caused no toxic damage to the animals even at the highest dosage of 8.5 % in the feed. In a 90-d feeding experiment on rats, oxidized polyethylene wax up to acid numbers 70 in dosages of 0.2, 1, 1.6, and

Table 26. Acute oral, subchronic, and chronic toxicity of montan wax derivatives

Wax	Chemical composition	Acute oral toxicity, LD_{50}, mg/kg	Subchronic toxicity, 90-d no-effect level ∗, mg/kg	Subchronic toxicity, 140-d no-effect level ∗, mg/kg	Chronic toxicity, 2-a no-effect level ∗, mg/kg
Acid wax (Hoechst wax S)	montanic acid $C_{16}-C_{36}$	>15.000 (rat)			
Ester wax (Hoechst wax E)	esters of montanic acid with ethanediol	>20 000 (mouse)		50 000 (dog)	50 000 (rat)
Ester wax (Hoechst wax KPS)	esters of montanic acid with ethanediol and 1,3-butanediol	>15 000 (rat)	50 000 (dog)		50 000 (rat)
Ester wax (Hostalub WE 4)	esters of montanic acid with glycerol		50 000 (rat)		
Partially saponified ester wax (Hoechst wax OP)	esters of montanic acid with 1,3-butanediol and calcium salts of montanic acid	>20 000 (mouse)		50 000 (dog)	50 000 (rat)

∗ Proportion by weight in the feed.

5 % in the feed produced no adverse effects in the animals. Histopathological tests showed no morphologically recognizable damage or changes caused by the waxes. No accumulation was observed in tissues, liver, or lymph glands. Fat and iron metabolism and spermatogenesis and oogenesis were unaffected (Table 27) [219]. Practically no negative effects were found in dermatological tests on rabbits. Polyethylene waxes and oxidized polyethylene wax show good COD elimination under sewage treatment plant conditions and no toxicity to fish or bacteria.

Paraffins and Microwaxes. Petroleum waxes have been used for decades as food additives, as wax coatings for cheese, in chewing gum, for upgrading food packaging, and in cosmetics and pharmaceutical products, without damaging human health. The toxicological properties of paraffins and microwaxes extracted from crude petroleum depend essentially on their composition and purity, particularly their residual aromatics content.

In a study of the toxicity of petroleum waxes, rats were fed with several paraffin products for 2 years. At a dosage of 10 % wax in the feed, no toxicological or carcinogenic effects were observed. Even on repeated application of petroleum waxes to the skin of mice and rabbits, no carcinogenic effects were detected [222].

Toxicological tests have been carried out with paraffins and microwaxes are mainly 90-d feeding experiments on rats. In these, varying toxicological effects were observed. For low molar mass paraffins, accumulation in the tissues and increased organ weights of the liver, kidney, spleen and lymph glands were observed. The most important histopathological findings were granulomata in the liver and histiocytosis in the lymph glands. These effects were not found with high molar mass waxes.

No toxic effects were found at a dose of 0.6 mg per kilogram of body weight and day for low molar mass paraffins (C-number maximum 25) and 1.8 g per kilogram of body weight per day for high molar mass paraffin (microwaxes, C-number maximum 42).

The latest results are published in BIBRA reports [223], [224], CONCAWE reports [225], and reports of the Toxicology Forum [226], [227].

Amide Waxes. The most well known amide wax, bis(stearoyl)- bis(palmitoyl)ethylenediamide, has an LD_{50} of >20 000 mg/kg (mouse). In determination of the chronic toxicity in a 2-a feeding experiment on rats, a non-effect level of 5 % in the feed was established [218].

Approval for Food Contact. On the basis of their low toxicity, a range of natural waxes, montan wax derivatives, amide waxes, polyethylene waxes, paraffins, and microcrystalline waxes have been approved for food contact by the health authorities of many countries [e.g., the German BgVV (formerly BGA), the U.S. FDA, and in Australia and Japan]. The products are also contained in the draft version of the EC additives list (Synoptic Document no. 7 of May, 15, 1994). Some of the waxes are approved in

Table 27. Acute oral, subchronic, and chronic toxicity of polyolefin waxes

Wax	Acute oral toxicity, LD_{50}, mg/kg	Subchronic toxicity, 90-d (rat) no-effect level ∗, mg/kg	Subchronic toxicity, 9-month (rat) no-effect level ∗, mg/kg
Polyethylene wax (Hoechst wax PE 520)	>15 000		85 000
Polyethylene wax oxidates			
(Hoechst wax PED 121)		16 000	
(Hoechst wax PED 522/PED 136)	>15 000	50 000	
Polypropylene wax (Hoechst wax PP 230)	>5000		

∗ Proportion by weight in the feed.

the European Directives 95/2/EC and 95/3/EC for food contact.

Registration According to EINECS/TSCA/AICS/DSL. Waxes are registered under the CAS numbers given in Table 28 in the European Inventory of Existing Chemical Substances (EINECS), the TSCA inventory in the United States, the Australian AICS inventory, and the Canadian DSL inventory.

Table 28. Registration according to EINECS, TSCA, AICS, DSL

Type of wax	CAS registry no.
Natural waxes	
Beeswax	[*8012-89-3*]
Carnaúba wax	[*8015-86-9*]
Candelilla wax	[*8006-44-8*]
Waxes based on montan wax	
Montan wax fatty acids	[*68476-03-9*]
Ethylene esters of montan wax fatty acids	[*73138-45-1*]
1-Methyl-1,3-propanediyl esters of montan wax fatty acids	[*73138-44-0*]
Calcium salts of montan wax fatty acids	[*68308-22-5*]
Montan wax glycerides	[*68476-38-0*]
Montan wax (crude montan wax)	[*8002-53-7*]
Polyolefin waxes	
Polyethylene wax	[*9002-88-4*] ∗
Ethylene	[*74-85-1*]
Polypropylene wax	[*9003-07-0*] ∗
Propylene	[*115-07-1*]
Polyethylene wax oxidates	[*68441-17-8*] ∗
Petroleum waxes	
Paraffin and hydrocarbon waxes	[*8002-74-2*]
Microcrystalline waxes	[*63231-60-7*]
Amide wax	
N,N′-Ethylenedistearamide	[*110-30-5*]

∗ In EINECS, polymers are registered only under the CAS registry no. of the monomer.

Waxes are not in the *MAK value list* for 1995.

Labeling According to GefStoffV, ChemG, and EC Guidelines. If they are pure and are not in the form of preparations with components for which labeling is compulsory (e.g., emulsifiers), waxes do not have to be labeled according to GefStoffV (October 26, 1993), the ChemG, Technische Regeln für Gefahrstoffe (technical regulations governing hazardous substances, TRGS) 200, and the EC Guideline 67/548/EC and adaptations and amendments.

Status According to OSHA. Paraffins are regulated by OSHA. Labeling is prescribed on packaging of paraffins (right-to-know label), in which warning of paraffin vapors is given. Paraffin vapors are classified as eye and respiratory irritants; they have the following exposure limits:

OSHA-PEL	2 mg/m^3
ACGIH-TLV	2 mg/m^3

Other waxes are not regulated by OSHA.

1. Introduction

1.1. Definitions of Weeds

Weeds are unwanted plants. They have been a problem since humans first tried to grow their own crops, only to find that other plants wanted to grow there as well. Several definitions of weeds are used. A common one is, "A weed is a plant out of place." EMERSON noted that, "A weed is a plant whose virtues have not yet been discovered." A useful definition of a weed is, "A plant whose negative values outweigh its positive values." The last definition introduces the concept that not every plant often considered a weed is necessarily all bad. It can have positive values as well, such as erosion control, the ability to fix nitrogen, feed and shelter for wildlife, etc. And all the definitions imply that being a weed is not a natural condition; Mother Nature does not decide whether a plant is good or bad. This decision is made by humans. Sometimes the decision is nearly unanimous, as with Canada thistle or field bindweed, two widespread, deep-rooted noxious weeds, while people may disagree about the relative positive and negative aspects of other plants. The point is that the designation of a plant as a weed is a human decision, not a natural one.

Genus and species of weeds mentioned by common name are listed in the following:

Arrowhead	*Sagittaria* sp.
Barnyardgrass	*Echinochloa crus-galli*
Bracken fern	*Pteridium aquilinum*
Broomrape	*Orobanche* sp.
Bull thistle	*Cirsium vulgare*
Bulrush	*Scirpus* sp.
Canada thistle	*Cirsium arvense*
Cattail	*Typha* sp.
Chara	*Chara* sp.
Cheat	*Bromus secalinus*
Chickweed	*Stellaria media*
Cocklebur	*Xanthium* sp.
Coontail	*Ceratophyllum demersum*
Crabgrass	*Digitaria sanguinalis*
Curly dock	*Rumex crispus*
Dandelion	*Taraxacum officinale*
Dodder	*Cuscuta* sp.
Duckweed	*Lemna* sp.
Elodea	*Elodea* sp.
False dandelion	*Hypochaeris radicata*
Fiddleneck	*Amsinckia* sp.
Field bindweed	*Convolvulus arvensis*
Field horsetail	*Equisetum arvense*
Foxtail	*Setaria* sp.
Henbit	*Lamium amplexicaule*
Johnsongrass	*Sorghum halepense*
Kochia	*Kochia scoparia*
Lambsquarter	*Chenopodium album*
Leafy spurge	*Euphorbia esula*
Mullein	*Verbascum blatteria*
Mustard	*Brassica* sp.
Naiad	*Najas* sp.
Nightshade	*Solanum* sp.
Nitella	*Nitella* sp.
Northern jointvetch	*Aeschynomene virginica*
Pigweed	*Amaranthus* sp.
Plantain	*Plantago* sp.
Pondweed	*Potamogeton* sp.
Prickly pear	*Optunia* sp.

(Continued)

Prostrate knotweed	*Polygonum aviculare*
Quackgrass	*Elytrigia repens* or *Elymus repens*
Rush	*Juncus* sp.
Russian knapweed	*Centaurea repens*
Russian thistle	*Salsola iberica*
Sacred lotus	*Nelumbo nucifera*
Sagebrush	*Artemesia tridentata*
St. Johnswort	*Hypericum perforatum*
Strangler vine	*Morrenia odorata*
Tansy ragwort	*Senecio jacobaea*
Waterhyacinth	*Eichhornia crassipes*
Waterlettuce	*Pritia stratiotes*
Waterlily	*Nymphaea* sp.
Watermilfoil	*Myriophyllum* sp.
Wild carrot	*Daucus carota*
Wild garlic	*Allium vineale*
Witchweed	*Striga* sp.
Yellow nutsedge	*Cyperus esculentus*

1.2. Losses from Weeds

The costs of unwanted plants to human activity are enormous (→ Crop Protection). They obviously interfere with the yield and quality of the world's crops, but their detrimental effects go far beyond that. They can also clog essential waterways and canals, poison livestock, cause dermatitis in humans, induce hayfever and other respiratory problems, create fire hazards, damage pavement in parking lots and along roadways, be unsightly, interfere with utility lines, block highway signs and reduce visibility at intersections, and occasionally produce attractive but poisonous fruit, leading to human health problems or even death. The total cost of weeds in monetary terms is unknown, and most estimates are highly inexact, but there is widespread agreement that the annual cost of weeds to society worldwide greatly exceeds 10^{10} dollars.

2. Biology of Weeds

2.1. Plant Types

2.1.1. Land Plants

Most weeds on land are grasses, sedges, or broadleaves.

Grasses. Grass seedlings have only one leaf as they emerge from the seed. Their leaves are generally narrow and upright, with parallel veins. Most grasses have fibrous root systems. The growing point on seedling grasses is sheathed, and located below the soil surface during the early part of their life cycle. Some grass species are annuals; others are perennials.

Sedges are similar to grasses except that they have triangular stems and three rows of leaves. They often are listed with the grasses on pesticide labels. Most sedges are found in wet places, but principal pest species are found in fertile, well-drained soils. Yellow nutsedge is a perennial weed species that produces rhizomes and tubers.

Broadleaves. Broadleaf seedlings have two leaves as they emerge from the seed. Their leaves are generally broad with netlike veins. Broadleaves usually have a taproot and a relatively coarse root system. All actively growing broadleaf plants have exposed growing points at the end of each stem and, in some cases, in each leaf axil. Perennial broadleaf plants also may have growing points on roots and stems above and below the surface of the soil. Broadleaves include species with annual, biennial, and perennial life cycles.

Others. Weeds not in the above groups include spore-bearing plants, as field horsetail and bracken fern; conifers, such as *Juniperus* sp.; and certain monocots, such as wild garlic, *Iris* sp., cattails, and rushes.

2.1.2. Aquatic Plants

Many aquatic plants are similar to land plants, and have stems, leaves, flowers, and roots. Most act as perennial plants – dying back and becoming dormant in the fall, and beginning new growth in the spring. They are classified as:

1) Emergent (emersed) – most of the plant extends above the water surface. Examples are cattails, bulrushes, and arrowheads.
2) Floating – all or part of the plant floats on the surface. Examples are waterlilies, duckweeds, waterlettuce, and waterhyacinth.

3) Submergent (submersed) – all of the plant grows beneath the water surface. Examples are watermilfoil, elodea, naiads, pondweeds, and coontails.

Emergent and floating plants, like some land plants, have a thick cuticle on their leaves and stems, which hinders herbicide absorption. Submergent plants have a very thin cuticle on their leaves and stems, and are very susceptible to herbicide injury.

Algae are aquatic plants without true stems, leaves, or vascular systems. For control purposes, they may be classified as:

1) Plankton algae – microscopic plants floating in the water. They sometimes multiply very rapidly, and cause "blooms" in which the surface water appears soupy green, brown, or reddish brown, depending on the algal type.
2) Filamentous algae – long, thin strands of plant growth that form floating mats or long strings extending from rocks, bottom sediment, or other underwater surfaces.
3) Macroscopic freshwater algae – larger algae that look like vascular aquatic plants. The two should not be confused, however, because their control is different. Many macroscopic algae attach themselves to the bottom and grow to be as much as 60 cm tall; nevertheless, they have no true roots, stems, or leaves. Examples are chara and nitella.

2.1.3. Parasitic Seed Plants

Dodders, broomrape, witchweed, and certain mosses are important weeds found on some agricultural, ornamental, and forest plants, living on and obtaining their food from the host plants. They can severely stunt and even kill the host plants by consuming the host plants' water, food, and minerals. These plants reproduce by seeds. Some also can spread from plant to plant in close stands by vining and twining.

2.2. Life Cycles

2.2.1. Annuals

Plants with a one-year life cycle are called annuals. They grow from seed, mature, and produce seed for the next generation all within one year or less. There are two types: summer annuals and winter annuals.

Summer annuals are plants that grow from seeds that sprout in the spring. They grow, mature, produce seed, and die before winter. Examples include crabgrass, foxtails, pigweeds, lambsquarters, Russian thistle, kochia, barnyardgrass, nightshades, and many others.

Winter annuals grow from seeds that sprout in the fall. They grow, mature, produce seed, and die before summer. Examples are cheat, henbit, fiddleneck, and chickweed.

2.2.2. Biennials

Plants with a two-year life cycle are biennials. They grow from seed and develop a heavy root and compact cluster of leaves (called a rosette) during the first year. In the second year they mature, produce seed, and die. Examples are mullein, bull thistle, tansy ragwort, and wild carrot.

2.2.3. Perennials

Plants that live more than two years, and may live indefinitely, are known as perennials. Perennial plants may mature and reproduce in the first year, and then repeat the vegetative, seed production, and maturity stages during several subsequent years. In other perennials the seed maturity and production stages may be delayed for several years. Some perennial plants die back each winter; others, such as trees, may lose their leaves, but do not die back to the ground. Most perennials grow from seed; many also produce tubers, bulbs, rhizomes (below-ground root-like stems), or stolons (above-ground stems that produce roots).

Simple perennials send down a tap root and form crown buds. They normally reproduce by seeds. However, root pieces left by cultivation can also produce new plants. They do not spread vegetatively without help from humans, or machinery. Examples include dandelion, plantains, curly dock, and false dandelion.

Bulbous perennials may reproduce by seed, bulblets, or bulbs. Wild garlic, for example, produces seed and bulblets above ground, and bulbs below ground.

Creeping perennials produce seeds, but also rhizomes or stolons. Many spread by lateral roots as well. Examples of creeping perennials include johnsongrass, field bindweed, Canada thistle, Russian knapweed, yellow nutsedge, and leafy spurge.

2.3. Reproduction

Seed distribution is a major method of disseminating weed species over space and time. Anderson [11] describes a seed as "a tiny encapsulated embryonic plant." From an evolutionary standpoint, plants do not necessarily gain much advantage by producing large amounts of biomass, so in general, those plants that produce the most biomass represent developed, cultivated crops. However, there is a great evolutionary advantage associated with producing many seeds, and weeds have developed this to a high art. There are many reports in the literature of astounding levels of seed production, each one seemingly exceeding the previous. Production of over 100 000 seeds per plant is relatively common, and at least one paper reports over 11×10^6 seeds from a single specimen of tumbling pigweed [12].

If one is concerned about next year, and most of us are, it is obviously advantageous to reduce or eliminate weed-seed production. This can be accomplished in a number of ways, including tillage, applying chemicals, or mowing. A word of caution is in order about mowing, however. Sometimes large weeds that have entered the bloom stage at the time of mowing may be able to form viable seeds even after they have been cut off. Mowing should be done prior to the bloom stage if at all possible.

Many weeds form seeds in response to day-length signals. Again, plants have evolved under the pressure to reproduce their kind, so it is not uncommon to see late-germinating annual weeds forming seed heads when they are only 5 – 8 cm tall.

Weed seeds can be spread in a number of ways. A common route is contamination in crop seed, which might be transported hundreds or thousands of miles. Seeds might also become attached to vehicles, articles of clothing, etc. Besides relying on man as a disseminator, weeds can be spread by natural means as well. Many weeds have developed ingenious adaptations to help them spread. For wind dispersal, several plant families have evolved attachments that permit them to float in the wind. Composites have a tiny parachute attached to each seed that helps them cover long distances. Russian thistle, the original "tumbleweed," is well-adapted for spreading seed by wind. It grows in a generally round form, and develops an abscission layer near the soil surface so that it can readily detach when it is mature. The seeds are held with varying degrees of firmness; thus, as the Russian thistle is bounding across the land, driven by the wind, some of the seeds are dropped more quickly than others, assuring that seed will spread over a considerable area.

Many weeds are spread by movement in water. Curly dock, for example, has corky "pontoons" around each seed. Numerous species are readily moved through irrigation water or in rivers. Any grower will confirm that weed problems are always more severe following a flood.

Many weed seeds have a sufficiently hard coat so that they can pass through the digestive tract of a bird, which of course means they can be transported for many kilometers. Some weeds have adaptations such that they are transported by animals to whose fur they have become attached. A good example is cocklebur.

The way weed seeds germinate may also be very important. Seed germination is a large topic in itself, and the biochemistry and physiology of the process will not be discussed here, but certain concepts do need to be explored. For example, seeds might not germinate because they lack the proper conditions to do so. They may lack oxygen, light, or moisture. Seeds that are buried too deeply might be perfectly capable of germinating immediately if exposed to the proper conditions, but fail to do so in the soil because they lack some particular requirement. These seeds are said to be "quiescent," a condition that might also be called "enforced dormancy." When a vegetation manager tills the soil, he may in the process inadvertently bring up a new crop of weed seeds that have only been quiescent.

Other weed seeds fail to germinate even under perfect conditions because they are "dormant."

This can be caused by a number of internal conditions. Weed-seed dormancy serves as a method of dispersing seeds in time rather than space. It is easy to see how this might be an evolutionary advantage. If 100 % of a plant's seeds germinated in a particular spring, they could be vulnerable to a sudden frost, a flood, or the farmer's plow. Unfortunately for us, Mother Nature has assured that some of the seeds will germinate the following spring, some the second year, some the third year, etc. This makes the grower's job much more difficult. The person who finds a way to destroy all the dormant weed seeds in the soil cheaply and efficiently might make a more major contribution to civilization than anyone who has ever lived, and would certainly become rich and famous.

The longevity or persistence of weed seeds in the soil can significantly influence management practices. Is plowing down weed seeds a good idea or a bad idea? It all depends on the seed persistence. Burying seed that tend to degrade rapidly in the soil is an excellent way of controlling that species. However, the seeds of many species can survive for years or even decades if held in the dormant or quiescent stage. Plowing those types of seeds down merely prolongs the problem. In general, grass seeds tend to be less persistent than broadleaf seeds. Grass seeds seldom persist more than ten years, and most of them are probably degraded within the first three years. Seed from many broadleaves, on the other hand, are able to remain viable for decades. Seventy percent of mullein seeds buried in the soil were found still to be viable after 80 years [13]. Of course, the record seems to be the seed of the sacred lotus, found in a Manchurian lakebed, believed to be about 1000 years old and still viable [14].

Many weeds, mostly perennials, can spread vegetatively. Stolons are above-ground, horizontal stems, rhizomes are underground stems, and roots can spread laterally to form new plants as well. Most broadleaf creeping perennials spread by lateral roots, whereas most creeping perennial grasses spread by rhizomes.

The productivity of the underground organs of a plant can be amazing. By the end of the third season of growth, a single plant of field bindweed [15] or Canada thistle [16] is capable of penetrating to a depth of 6 – 7 m. A single Canada thistle seedling has produced a patch 18 m in diameter in three years [17]. A single tuber of yellow nutsedge planted in soil produced 1900 plants together with 6900 tubers in a patch 2 m across in one year [18]. All of this represents a tremendous productive capacity, making elimination of creeping perennial plants very challenging. It also helps explain why controlling a perennial plant while still a seedling and before it produces underground propagules is highly desirable. Understanding the methods by which weeds reproduce is the first step in designing intelligent control programs.

2.4. Interference Between Crops and Weeds

Interference is the detrimental effect of one plant on another. This may include: competition, which is the contest for limited resources within a habitat, and/or allelopathy, which is the harmful effect of one plant on another through the production of chemical compounds. Whether parasitism (dodder in alfalfa) or mechanical damage (lodging ryegrass in wheat) should be classed as interference is open for discussion.

2.4.1. Competition

Physiologically, crops and weeds are equivalent, in that both require the same resources from the environment for growth and development. Primary resources are water, nutrients, and light. When unwanted plants use up some of the resources, they are no longer available to the crop. Nearly always, this restricts crop growth and reduces yield.

Competition occurs when a resource becomes limiting. Sometimes a resource is so abundant that competition never enters the picture. If one species (crop) is able to use a resource more effectively, it may "out-compete" another species (the weed), but some fraction of the resource has nevertheless been diverted to the weed, and is thus not available to the crop, so the crop will have been reduced. For example, maize may reduce weed growth more than the weed reduces the maize, but the yield from weedy maize is still less than that from clean maize. If no use is made of the weeds for feed

or some other purpose then those resources have been wasted.

Sometimes a crop species is selected precisely because of its competitive nature. Sorghum sudangrass, for example, is rapid growing, grows very tall and thick, and can outcompete many weeds. Fall-planted canola requires weed control early in its cycle to ensure an adequate stand, but once established it outcompetes most weeds. Barley is a better competitor than wheat, and growers sometimes choose to raise barley if confronted with a weed problem that cannot be controlled by other methods. At the other extreme, onions grow slowly, barely cast a shadow, and prove very poor competitors indeed.

Two major factors are important in competition. One is the level of weed infestation. It is no surprise that as weed density increases, crop yields decline, and the whole purpose of a weed control system is to prevent that from happening. Establishing an economic threshold level is desirable, but very difficult. Leaving a few weeds in a field may have a sufficiently small effect on the crop yield in that particular season to make it non-economical to apply a control measure, but the long-term effect of allowing weeds to go to seed is difficult to predict. If a 40-year supply of seeds of a particular species is already present anyway, the grower might be well advised to forego a spraying operation during the year in question.

Figure 1. Treatments in an experiment to determine how long weeds can be left undisturbed before they are removed without reducing crop yield

The other major factor involves the time of competition. There are two important questions related to that subject. First, how long can one leave the weeds in place before they must be removed in order to prevent crop damage? Figure 1 illustrates the treatments involved in studying this question. Certain plots are kept weed-free all season. In other plots, weeds are allowed to grow for varying lengths of time before they are removed. A typical result would be that shown in Figure 2, from which it is apparent that if the weeds were removed within about four weeks they would not reduce the crop yield at all in this case. Other situations might lead to very different results.

Figure 2. Typical results from the experiment shown in Figure 1

How might this information influence management decisions? It could help the manager decide between a preemergence and a postemergence herbicide. If competition begins very early in the growth of the crop, perhaps too much crop loss would have occurred by the time a postemergence herbicide was applied and had become effective. On the other hand, if the weeds do not compete for 4 – 10 weeks there might be advantages in considering use of a postemergence herbicide, waiting to see which weeds are present and to what extent. A long-standing "theorem" of weed control is that "weeds cause most damage to the crop early in the life cycle of the crop." It is true that weeds that emerge early and are left uncontrolled will be the ones that ultimately cause the most damage – but it is not always true, indeed often is not true, that competition begins early. A better generalization is "competition occurs when a resource becomes limited." That may be weeks or months after the crop emerges.

The second question involving timing is: How long must one keep a field clean of weeds before the crop has developed to the point that it can take over? This is studied in experiments like that illustrated in Figure 3, in which the plots

are kept clean for varying lengths of time, after which the weeds are allowed to grow. This may result in a graph similar to that depicted in Figure 4, which shows that the crop in question needs to be kept clean for about eight weeks; thereafter, the crop itself can prevent further weed seedlings from developing.

Figure 3. Treatments in an experiment to determine how long weed control must be maintained before the crop can prevent weed invasion

Figure 4. Typical results from the experiment in Figure 3

Why might this information be helpful in making management decisions? It might influence whether one would select a soil herbicide of long or short persistence in the soil. For a crop that develops and takes over rapidly, a short-persistence herbicide, perhaps the cheapest one, might be quite satisfactory. The information could also influence how late cultivation must be continued, and whether or not a late postemergence treatment should be applied.

When these two questions are answered, the results can be plotted on the same graph, as shown in Figure 5. This graph may at first appear confusing, but remember that the two lines were obtained from separate experiments. The two plots together reveal the "critical period of competition": the period between the time when the first line starts downward and the second line levels off, in this case approximately 4 – 8 weeks after crop emergence.

Figure 5. Results shown in Figures 2 and 4 superimposed on one graph, showing the "critical period of competition"

Figure 6. One line of a stairstep apparatus used to separate mechanisms of allelopathy from competition. Test lines contain pots of maize alternating with pots of *Setaria faberii*. Control lines contain only pots of maize [19].
a) Supply reservoir; b) Culture pots; c) Collection reservoir with float switch; d) Pump

2.4.2. Allelopathy

Allelopathy is the term used to describe chemical warfare between plants. This phenomenon may in fact be very common, but it is largely unrecognized. A well-known example of allelopathy involves the black walnut, which is known to inhibit plant growth around its base, but there are many other examples as well. Thus, ground-up quackgrass rhizomes distributed over the surface of the soil will essentially prevent emergence of alfalfa seedlings. Allelopathic chemicals may be released from a plant's roots, leaves, stems, berries – even as a gas from the leaves. A very large number of plants have been shown to be allelopathic.

Distinguishing in the field between interference due to competition and that from allelopathy is very difficult. Sometimes this is attempted in a greenhouse by growing the weed and the crop in separate pots but on a stairstep arrangement so that leachate from the weed is transferred downward into the crop (Fig. 6). Crop growth in a series of that type is compared to the growth of crop in a series in which the weed is not included. Competition is no longer a factor, because all the plants have plenty of minerals, nutrients, and sunlight, but the crop might still be inhibited by leachate from the weed roots.

2.5. Biological Variability and Adaptability in Relation to Control Systems

2.5.1. Species Shifts

There are literally hundreds of species in a particular climatic zone that might become important as weed species. Those species that are more adapted than others to a particular set of cultural practices will tend to become dominant. Therefore, when such practices are changed it may lead to drastic changes in the species present. This might involve tillage, flooding, drainage, mowing, grazing, or use of a herbicide. If whatever practices are applied to the field prove detrimental to the dominant species, then other species more adapted to the new practices will replace the original ones. For example, flooding for 2 – 4 months might eliminate quackgrass, but it offers excellent conditions for the invasion of aquatic-type weeds. Similarly, the use of a herbicide can cause a rapid buildup of species that are tolerant to it.

Species shifts should be expected regardless of the weed-control method employed. They can occur rapidly, even within a single season, and they must be accepted as a fact of life. Avoiding detrimental shifts requires astute management. This might include herbicide combinations, herbicide rotations, and the use of a combination of nonchemical methods to help make life miserable for surviving weeds.

2.5.2. Resistance Development within a Species

Most species contain many different individual genotypes. It should not be surprising that these may differ in their susceptibility to a particular herbicide. If a herbicide is applied consistently over a number of years, individuals within the species that have genetic resistance to the herbicide will survive and flourish after the demise of its sensitive siblings.

This process takes more time than the species shifts discussed above. Certain herbicide families seem to develop resistant populations rapidly, whereas other families develop resistance slowly or not at all. It seems to be a question of gene frequency; i.e., the number of individuals in a given field with the altered gene for resistance.

Most scientists now believe that genes for resistance to various herbicides are already present in the population even before a herbicide is introduced. Control initially may be excellent, 99.9 % or greater, but a few surviving individuals will remain. Most of the cases of herbicide resistance now being studied are examples of incomplete dominance, meaning that when homozygous resistant and suceptible individuals cross, all the offspring are resistant enough to survive another herbicide application. The resistant survivors can then proliferate at a relatively rapid pace, sometimes resulting in a field-wide infestation of the resistant weed within five or six years.

What can one do about this? Weeds are not like insects. They are anchored, and they do not fly away. Methods of preventing the development of resistance are primarily extensions of

common sense, and they have not changed over the years.

1) Use other methods of weed control in conjunction with herbicides. This may include cultivating row crops, flaming, delaying seeding to allow mechanical control of the first flush of weeds, drainage, etc.
2) Rotate crops regularly, when possible. Switching from a winter crop to a spring-planted one provides an opportunity to prepare the land at a different time of the year and perhaps kill the resistant individuals. Or by shifting to another crop it may be possible to use herbicides to which the resistant weeds are susceptible.
3) If crop rotation is not a good option, rotate herbicides annually. To be effective, the alternate herbicide must be of a different type than the one originally used, one whose biochemical mechanism of lethal action is different.
4) Resist the temptation to use higher application rates when the effectiveness of weed control starts to decline. Uncontrolled individuals in the population are genetically resistant, and increasing the herbicide dosage will probably not kill them anyway. Heavier application will simply eliminate the less resistant types, and perhaps injure the crop enough to reduce its competitiveness, permitting the most resistant types to flourish. Higher than normal application rates may actually increase the rate of resistance development.
5) Finish the job if at all possible. Hand-weeding on a 2000-ha wheat ranch is not possible. But in small fields with row crops this may be an extremely inexpensive remedy in the long term. If a new herbicide provides 99 % control the first year, the remaining 1 % might be genetically resistant, and this is the proper time to eliminate them, while they are still few in number.
6) Herbicide combinations are generally used to increase the number of weed species controlled. Such a combination will slow the development of resistance only in weeds that both herbicides affect. A species controlled by only one of the herbicides will develop resistance just as rapidly as if that herbicide were used alone.

With all the methods outlined above, it is important that preventative procedures be instituted before resistance becomes evident. By the time resistance becomes obvious there will be large numbers of resistant seeds in the soil, so even eliminating all the resistant-type plants at this late date will fail to solve the problem. Especially if the seeds are long-lasting, the infestation may persist for many years.

3. General Concepts Underlying Weed Control

An important principle to remember is that weed control is part of a more general problem – vegetation management. This involves fostering beneficial vegetation and suppressing undesirable forms. It is a broader concept than simply seeking out plants that are considered generally to be undesirable and destroying them. Growing a vigorous and healthy crop can also contribute greatly to the suppression of undesirable plants.

Specific components within a plant population respond to changes in other components. It would be short-sighted to believe that it is possible to control one plant species without affecting other components. The effects in question might well be desirable (i.e., more productive maize or sugarbeets), but they might also lead to the invasion of even more serious weed pests.

A single plant species is seldom able to exploit all the resources of a habitat, and one rarely finds a natural habitat consisting of only one species, because a mixture of species can better take advantage of the resources available. Yet much of agriculture, is devoted to growing monocultures. This puts great pressure on the system for invasion of the crop by other species that are taller, deeper-rooted, shallower-rooted, etc. In other words, a monoculture leaves unfilled "niches." *Niche* can be defined as a microhabitat potentially suitable for supporting a particular organism – a species' "place" within a community; i.e., its place with respect to space, time, or function within that community. Weed control largely consists of reducing the number of niches, or disturbing unfilled niches in such a way as to make them unfavorable for invasion by weeds. Reducing the number of unfilled

niches might be accomplished through changes in planting arrangement, adjustment of the planting time, selection of more competitive varieties, alteration of irrigation systems, etc. Niches might be disturbed in any of several ways: physically, biologically, or chemically.

Intelligent weed control thus involves the management of a complete system, not just the simple act of killing an individual species.

4. Physical Methods of Weed Control

Physical/mechanical weed control includes the physical or mechanical act of hand-pulling, hoeing, cutting, digging, tilling, burning, flooding, or mulching weeds as a way of removing them or preventing their growth. Humans have been fairly inventive in devising methods for combatting weeds, but many of the physical methods used today differ little from those used 100 years ago.

4.1. Manual Methods

Hand Weeding. In some cases, grasping a weed and pulling it out of the soil may be the only practical method for removing weeds without simultaneously damaging the crop. Even so, small seedlings of crops may be uprooted and damaged when nearby weeds are pulled out. Hand-weeding is labor-intensive and slow. Because hand-weeding is usually delayed until weeds are easily seen and also large enough to grasp, competition with crop plants and yield losses may already have occurred before the weeds are removed. In rainy weather, hand-weeding becomes difficult, impractical, and possibly damaging to the crop.

Hand-Held Tools. Use of hand-held tools makes weeding a faster and easier process compared to hand-pulling of weeds, but it retains all the general advantages and disadvantages of hand-weeding. Also, the act of hoeing or cutting may simply transplant a weed, and the use of hand-held tools may damage certain root and tuber crops. In small areas, such as home gardens, hand-weeding (with or without tools) may nevertheless be the only practical way to get rid of weeds.

4.2. Tillage Methods

Animal-Pulled Tools. The use of animals to pull a cultivator makes weeding faster and easier than hand methods. Animal-traction cultivation between crop rows may not control weeds in the crop row, but it can greatly reduce the time required for in-row hand-weeding. Crops to be managed in this way must be planted in rows or hills, and the rows and hills must be spaced far enough apart to allow the animal, tool, and operator to pass without damaging the crop. In some crops, the right implement operated at the correct speed can throw enough soil into the crop row to smother and control small weeds without harming the crop. Even so, injury to the crop may result through cutting roots located below the soil surface, or damaging edible rhizomes or roots.

Cultivation may be difficult to accomplish and also ineffective in wet weather, and it is impractical for steep lands. Though the method requires no fossil fuel to power a tractor, it does presuppose feed for the draft animals. Additionally, a farmer must invest specifically in an animal (or two) and an appropriate implement, or contract the work to someone else.

Tractor-Powered Tillage. Various sizes and types of tractors have in many places come to replace draft animals for cultivation in an effort both to control weeds and to provide improved crop-growing conditions. Tractors greatly increase the amount of land area one person can cultivate, but they also have disadvantages: they are expensive to purchase, require petroleum fuel (also expensive), require maintenance and spare parts, need trained operators, are unsuitable for operating on steep slopes, and sometimes lead to soil compaction.

Delayed tillage is a technique whereby a seedbed is prepared, weeds are allowed to germinate, and then shallow tillage is performed before most of the weeds have time to emerge or grow very large. This practice controls many weeds before the crop is planted, but is effective only when there is enough moisture to encourage weed-seed germination, and where enough time and labor are available for conducting an extra operation.

Blind Tillage. With blind tillage, fields are subjected to shallow tillage after the seed has been planted but before crop plants emerge. Success in this case depends on (1) weeds germinating before or with the crop, and (2) a crop – such as maize or sorghum – that is tolerant of physical disturbance.

Various types of implements can help control weeds growing in the crop row. Some, such as "finger weeders," are already commercially available. Others, which may involve color discriminators, TV cameras, and other "high-tech" instruments, are still under development.

There are limitations associated with all types of tillage. While dry season tillage can bring rhizomes, tubers, roots, and other plant parts to the soil surface to be killed by drying, the process requires energy, and plant parts are sometimes dragged into uninfested areas of the field, thus spreading the problem.

4.3. Mowing and Cutting

Weed plants can be mowed or cut off near ground level using hand-held, animal-pulled, or power-driven tools. While this practice does effectively kill some annual weeds, it is ineffective against weeds that are able to regenerate after being mowed.

Removing part of a weed by mowing often helps control weed-caused problems (competition, interference with the harvest, and the production of weed seed). Also, the dead plants can help protect the soil against erosion caused by wind and rain, and from compaction from vehicular or foot traffic.

While often suitable for pastures, ditch banks, roadsides, and the space between rows of woody perennial crops, mowing is ineffective for controlling creeping or low-growing weeds that escape most of the mowing action.

Principle of Carbohydrate Starvation. Removing the top part of perennial plant (shoots and leaves) by tillage or mowing interrupts the vital flow of carbohydrates to below-ground storage organs (roots, tubers, rhizomes). When the aerial part of a plant is removed, the plant uses root reserves to produce new top growth, and it continues to use root reserves for a short period even after new growth is visible. Repeated hand-cutting or mowing to remove weed top growth 10 to 15 days after new growth appears is the most efficient method for depleting root reserves in most species. To be effective, the process must be repeated several times without ever allowing the above-ground portion to grow for more than approximately 15 days after emergence, or more than about 3 weeks between tillage operations.

4.4. Flooding

Flooding, a centuries-old weed control method for rice production, is also used in nurseries, for fields receiving transplanted crops, and for direct-broadcast seeded fields. For crops such as rice that can withstand aquatic conditions, flooding can be an effective method of controlling weeds. For crops that cannot withstand aquatic conditions, flooding can nevertheless be used to control weeds during a fallow season or a rotation period. For example, a perennial grass might be killed by flooding so that after the water has been removed an upland crop can be planted.

Flooding requires relatively level fields with soils that prevent the water from quickly percolating into the ground. Accompanying requirements include a perimeter barrier (levee or dike) to contain the water, a method for draining the water off the field, a water source that provides enough volume for the depth and duration needed to prevent weed emergence or to kill existing weeds, and ability on the grower's part to practice flooding effectively.

4.5. Mulching

Mulching for weed control involves the use of any of several materials to prevent light from reaching the soil surface. Germinating weeds then die for lack of necessary light. Mulching also may conserve moisture by reducing runoff and evapotranspiration, and by lowering the temperature of the soil. Mulching may add organic matter to the soil as well. It is most frequently practiced with high-value crops grown on small areas.

Plant parts (leaves, stems, etc.) are commonly used as the mulching agent. Plants may

be mowed and left where they fall, or gathered, stored, and used for mulching later. Rice straw, rice hulls, sawdust, bark chips, newspaper, and large but immature weeds that have not formed seed are all potential mulching materials. Care must nevertheless be taken to assure that plant mulch does not contain weed or crop seeds (weed prevention).

Thin sheets of polyethylene are used as a mulch in some farming operations. Black plastic can absorb heat, raising the air temperature around crop plants and accelerating their growth, whereas clear plastic traps the sun's energy to heat the soil and air under the plastic.

These conditions can be helpful in certain situations, but damaging in others. The temperature under clear plastic can become high enough to kill many organisms, including seeds and vegetative parts of some weeds. Plastic mulch involves the cost of purchase as well as that of the labor (and possibly specialized equipment) to place it in the field. If the plastic does not self-disintegrate, labor will also be required later to remove it. Some perennial weeds, such as yellow nutsedge, can penetrate plastic mulch.

Mulching can be combined with inter-row cultivation in the case of row crops. Mulch is placed in the crop row, either around an established crop or with holes cut to allow crop seedlings to emerge. Cultivation is then used to control weeds between the rows. Obviously, mulch placed between crop rows would not control weeds within the row.

4.6. Use of Heat

Heat application is often an economical and practical means of controlling weeds. It greatly reduces the amount of hand labor required, particularly in combination with other weed-control practices. Heat is also used widely to dispose of accumulated vegetation that is unsightly or poses a health hazard.

Burning cannot be equaled for controlling weeds in some situations. For example, existing vegetative cover with low economic value can be eliminated in this way from rangelands, permitting the establishment of more desirable grasses. Controlled burning has been used for many years as a cultural practice in forest management to eliminate excessive fuel accumulation, thus reducing the risk of forest fires. Site-preparation to establish new plantings and to release desirable species is often accomplished by controlled burning. A regimen of three to four annual burns is one of the least expensive ways to remove hardwood undercover in a pine forest. Pine trees are capable of withstanding heat that kills undesirable hardwood species. Suitable precautions are of course required to prevent the fire from escaping.

In seeking to take advantage of flame, man has tried to improve upon nature. Special equipment designed to burn petroleum products as fuel is able to create temperatures of about 1 100 °C that kill only young plants. Flame may be used either as a nonselective method of killing all plants, or to kill weeds selectively without injuring a crop. A hooded burner is often used for selective flaming, but it can also be adapted for nonselective use.

Flaming does not necessarily kill by direct combustion. Burning of plant tissue occurs only after repeated flamings, and it should be kept at a minimum to avoid crop injury. The death of a plant by flame appears to be associated with injury to cells of the leaves and stem. With the cells destroyed, the seedling has no means of recovery or regeneration. Selective killing of weeds and crop plants with flame is accomplished in several ways. Different types of plants are able to withstand different amounts of heat, depending on their stem structure, age, size, and shape. Weed kill is accomplished by moving an intense flame along the base of a weed-infested crop. The intensity and duration of exposure are important factors in obtaining effective results. Desired exposures are obtained by varying the tractor speed. The size and intensity of the flame are controlled by an orifice tip and varying the fuel pressure. The critical temperature above which cambium cells are subject to injury appears to be about 55 °C. An initial flaming on cotton is normally conducted when stems are about 0.5 cm in diameter at ground level. At this stage, the cambium layer in the cotton is protected by an insulating layer. Succulent weed seedlings have no such protection, and the heat needs to travel only a short distance to reach vital cells. The larger leaf-surface area of the weeds absorbs more heat than the round surface of the cotton stem. Selective flaming is performed in a wide variety of crop, including cotton, corn, soybeans, and grain

sorghum, as well as such other crops as blueberries, raspberries, and grapes. Experimental use of flame has shown promise in such vegetable crops as onions, carrots, asparagus, and potatoes.

Alfalfa is flamed to control dodder and other weeds; flame is also used to control weeds in certain grasses and to obtain cleaner grass-seed crops; potato vines are flamed when the tubers are mature to facilitate mechanical harvesting; and drainage and irrigation ditches are kept free from weeds by nonselective flaming.

The proposed objectives of using heat for weed control should be examined carefully. Very often, too much is expected from burning or flaming. People not fully acquainted with the limitations of these methods are then disappointed by the results. For example, open-field burning is more effective in disposing of accumulated vegetation than in the killing of weeds. It is often used after weeds have already matured and viable seeds are present. In such cases, fire seldom reduces the viability of scattered seeds enough to produce any practical benefit.

Several flaming applications may be necessary to ensure satisfactory weed control. The initial cost of a flamer is often much greater than that of a sprayer. In addition, the heat generated by the burner may prove to be more than the operator can handle. If the weeds in question are as resistant to flame as the crop, then selective flaming is not feasible. A flamer is also generally more difficult to adjust than a sprayer. In most crops, weed control cannot be achieved with flame alone. It is most effective when used as a supplement to other weed-control practices, such as pre-emergence and postemergence herbicides (see Chap. 7).

Despite its limitations, flaming also has a number of important advantages in weed control. With the increased use of herbicides and increasing awareness and concern regarding residues in soil and crops, the fact that flaming is free of any residue hazard has special merit. With a well-adjusted flamer, results are usually not greatly influenced by environmental conditions, and there are no drift hazards to adjacent crops. Flaming can often reduce other plant pests such as insects and diseases, facilitate mechanical harvesting by eliminating trash, serve as a control measure when the field is too wet for mechanical methods, and permit almost immediate inspection of weed control.

The use of hot water has been tested as an alternative approach to weed control. It appears to kill some weeds more effectively than others and is not expected to be effective on perennial weeds.

5. Biological Control of Weeds

Biological control of weeds consists of the deliberate use of natural enemies to reduce the population of a target weed (→ Biological Control). In other words, it is the control of weeds by biological organisms (excluding man). Biocontrol methods include herbivore management as well as classical and inundative approaches.

5.1. Herbivore Management

This approach involves controlling weeds by managing animals, which can include geese, sheep, goats, grass carp, manatees, marisa snails, and others. The animals are in turn manipulated directly by man.

There are reports of success in cleaning up brushy, weedy pastures with a combination of cattle, sheep, and goats. These animals tend to eat different plants, so with careful management many undesirable weeds can be kept suppressed. Sheep have been used to control tansy ragwort and leafy spurge. Use of grazing animals requires considerable organisation and supervision. Grazing must be intense enough to force the animals to eat some of the less desirable weeds; on the other hand, they must not be allowed to overgraze a pasture to the detriment of the grass. Some innovative work is being conducted in "bonding" animals of different species so that they will graze together and perhaps provide some protection against predators. Also, methods are being developed for cheaper fencing methods based on a remote "shock" treatment, where a receiver and shocking device around the animal's neck senses a single wire on the soil surface. The animals soon learn to avoid getting too close to such a "fence."

Before the introduction of selective herbicides, geese were commonly used to control weeds in peppermint, strawberries, and other

crops. Herbivorous fish have been used for successful control of aquatic weeds. Grass carp, which are sterilized before release, have been used with varying degrees of success. "Sea cows" or manatees have been used to help keep canals clean. These are large aquatic mammals that are able to eat large quantities of aquatic vegetation. Unfortunately, vandalism and injury from boats have reduced their number and limited their success.

Weed control by herbivore management is not without costs. The animals must be bought, watered and fed, protected from predators, and controlled so that they eat weeds in all areas of the field (not just the shady spots). Other practical problems arise as well, such as the fact that the animal population remains constant and does not respond to increases or decreases in weed populations.

5.2. Classical Biological Control

Biological control involves the importation of exotic natural enemies of a particular weed species. These have mostly been insects, but can also include microorganisms. Such biocontrol agents are most successful against imported weeds, because the corresponding biocontrol agents are imported with added care to ensure that their natural enemies are left behind.

Preliminary determinations must be made on the feasibility of importing an insect for a particular weed. This involves establishing the severity of the weed problem and the weed's relative taxonomic relationship with desirable crops.

Foreign exploration is carried out in that area of the world where the weed itself originated. Associated enemies of the weed are studied, and the specificities of various insects are determined. A geographic distribution of the proposed biocontrol agent that coincides exactly with the geographic distribution of the weed, provides relatively good assurance that the insect in question is restricted to that particular weed. The taxonomy of the weed is studied as well, and if it is closely related to a desirable crop, extreme care must be taken to make sure that the insect will not attack the crop. For example, an insect known to control mustard weeds (*Brassica* sp.) would be viewed with great skepticism because of the existence of numerous *Brassica* crops, such as cabbage, cauliflower, and broccoli.

The most critical test is the "starvation" test. In this case, the biocontrol agent is caged with a large variety of desirable plants. To pass the test, it must starve to death before it will eat any plant other than the target weed. On rare occasions, limited feeding on another species is allowed if it does not present an economic threat. For example, the cinnabar moth, imported to control tansy ragwort, also eats dusty miller, an ornamental that was judged not sufficiently important to halt the project.

Once a biocontrol agent has passed its specificity tests it is imported, after which it undergoes a period of quarantine. This is a time to inspect for accompanying predators and pathogens, and to make quite sure that no other insect has inadvertently been included in the shipment. The species is then introduced into the area where control is intended, and nurtured as much as possible. If the insect survives but spreads only slowly, governmental agencies may physically assist in the spread of the insect.

Classical biological weed control generally follows a cyclical pattern; i.e., as the predator multiplies, the weed population declines. This causes some of the predators to starve, and the insect population then declines, with a subsequent increase in the population of the weed. The cycle continues indefinitely. Success in such a program depends upon whether or not the predator can maintain the weed infestation mostly below its economic threshold level. Classical biological control generally does not work in cropland, because the economic thresholds are too low and the process is too slow. It is most successful in rangeland and waste areas.

Examples of successful programs include prickly pear cactus control in Australia by the moth *Cactoblastis cactorium*. In the United States, St. Johnswort has been controlled with the Chrysolina beetle, and tansy ragwort has been controlled with the cinnabar moth and the flea beetle. A rust has been used for control of rush skeletonweed in Australia. Several other agents have been released as well, and early evaluation suggests eventual success.

Some of the desirable aspects of classical biological control include the fact that there are no chemical residues and no drift hazard, it can work well in areas inaccessible to other meth-

ods, it is self-perpetuating, it is highly energy efficient, and it is almost always highly selective. Possible disadvantages include disagreements over whether a particular species is a weed in all situations. Moreover, biological control is usually not effective in low threshold situations, it controls only one weed species (whereas a complex of weeds is usually present), it may be too slow for cropland, any errors in introduction may prove much less reversible than mechanical or chemical mistakes, and natural enemies and weather may limit its effectiveness. Another consideration, neither advantageous nor disadvantageous, is that there is no profit motive for private enterprise to become involved in classical biological control, so the government must pay for the anticipated benefits to private businessmen (growers). There is also always the possibility of the development of resistance. This is likely to occur very much more slowly than with chemicals, because as the target weed evolves, the predator might also evolve, which is of course impossible with a herbicide.

5.3. Inundative Biological Control

Inundative control agents are often called "bioherbicides." This method involves the periodic release of a very large population of a particular biocontrol agent so that it simply overwhelms the target weed. Suitable agents are microbes, either bacteria or fungi. Such a biocontrol agent is not self-perpetuating at a level sufficient to maintain adequate long-term control.

Marketing and usage is the same as in the case of chemical herbicides; the agent is mixed with water and sprayed on the field. At least three such products have been introduced commercially. Collego is used in rice for control of northern jointvetch. Devine is used for control of strangler vine in Florida citrus. Luboa-2 is used for control of dodder on soybeans in China. A number of other similar products are nearing commercialization.

Some of the desirable aspects of inundative control agents are that they are probably safer to humans than many chemical herbicides, they are not likely to harm non-target plants to a significant extent, and they may control certain weeds for which no chemical herbicides are available. Disadvantages include the control of only one weed species, so that it will probably still be necessary to mix the control agent with chemical herbicides, thus adding to the cost. Bioherbicides are probably affected more by the environment than are chemicals, though the latter can also be affected. Their shelf life is an additional concern for the marketing organization. In contrast to classical control methods, the person who benefits from inundative control pays the cost. The process of preparing a bioherbicide might be patentable, but the agent itself is not.

Clearly, biological control is an important approach to weed control in many situations. It can be a safe, highly cost efficient method, and it can provide an alternative to chemical herbicides. Because of the nature of the process, it is unlikely ever completely to replace other methods of weed control. Considerable research is being conducted around the world to supplement existing biocontrol agents.

6. Controlling Weeds by Habitat Management

Managing the habitat to favor desired vegetation and hamper undesirable vegetation is at the very core of weed control. Yet, it is the place where the "art" of weed management comes in, rather than the "science." Certainly everything that happens is based upon scientific principles, but habitat management sometimes is difficult to describe in a "1 – 2 – 3" manner. More than anything, it is the "art of good farming," and some people are naturally better at it than others.

There are several specific ways in which one might possibly encourage desirable vegetation and hinder weeds. One of these involves crop competition. Selecting a more competitive species (e.g., planting barley instead of wheat), growing a taller variety, growing earlier-season crops so that they emerge before most of the weeds, etc., are all measures designed to take advantage of competition from the crop on the weeds. Because the objective is to grow high-yielding and high-quality crops anyway, this approach amounts essentially to "free" weed control, and it can be quite significant. Sudangrass is sometimes planted primarily as an interim crop, selected because it emerges quickly and grows tall, thus protecting the soil from erosion

and competing effectively with later-emerging weeds. Irrigated alfalfa grown for hay can noticeably reduce the stand and vigor of patches of Canada thistle. The alfalfa is also deep-rooted, and it can compete directly, allowing the alfalfa to respond more quickly to periodic mowing than the thistle.

Planting density and arrangement can be manipulated to increase the competitiveness of a crop. Many row crops are traditionally grown in 1-m rows, primarily because that is what was required to permit a horse to walk between the rows for tillage purposes. Clearly, that is no longer needed, and a considerable trend toward narrower row spacing has been evident. Narrow-planted maize is more competitive to weeds, and it can lead to higher yields than maize planted in wide rows. Snap beans have been successfully grown in a solid seeding, but this method is hazardous because it apparently reduces the air movement among the beans to such an extent that white mold becomes a more serious problem.

Crop rotation has been shown to be highly desirable in many ways, including insect control, disease control, unknown soil factors, and certainly weed control. If alternative crops are available, ones that will yield an economic return to the grower, then this is a cheap and simple weed-control method. Planting in the spring rather than in the fall allows spring tillage, thus destroying winter annual weeds that may have built up with previous winter annual crops. Switching to a row crop may allow for different tillage systems than with a solid-seeded crop. Rotating to a different crop may also permit use of a different herbicide program, thus helping prevent species shifts and the development of resistant weed populations.

Other methods have proved successful for good managers as well. Placing the fertilizer in such a way as to benefit the crop while benefiting the weeds as little as possible has helped. Using delayed tillage or blind tillage – with careful attention to timing – also is useful. Adjusting mowing height can be important in turf areas. On golf courses, controlling traffic may reduce a problem with prostrate knotweed, allowing the grass itself to control the weed. Drip irrigation tends to water a crop more efficiently than it does a weed. Adroit grazing management, including rotation of pastures, proper placement of water and salt, etc., may be beneficial to pasture grasses at the expense of grass weeds.

Although habitat management is difficult to define and direct in specific terms, it may in fact be the most significant method of all for controlling weeds.

7. Chemical Control of Weeds

7.1. History and Introduction

The science of herbicides is relatively new, but the use of herbicides is not. Indeed, chemicals were used even in ancient times to control unwanted vegetation. In the Fourth Century B.C., THEOPHRASTUS [20] reported that trees could be killed by pouring oil (presumably olive oil) over their roots. PLINY [21] referred to the Greek DEMOCRITUS (Fifth Century B.C.), who proposed that forests could be cleared by sprinkling the tree roots with hemlock juice in which lupin flowers had been soaked. Application of salt to the fields of enemies was often used as means of punisment; thus, in 146 B.C., following the sack of Carthage, the Romans spread salt over the surrounding fields to prevent the growing of crops.

Chemicals were first used for selective weed control in the late 1890s. Several copper salts, iron sulfate, sulfuric acid, and other chemicals were used rather extensively in Europe for control of certain broadleaf weeds in small grains. Usage of these materials never became highly popular in the United States, however. Through the 1920s and 1930s, considerable amounts of nonselective-type herbicides were used, particularly to control perennial weeds. These included sodium chlorate, the borates, and inorganic arsenicals. During the 1920s and 1930s plant physiologists were also working diligently with several growth-regulator compounds. One of these, 2,4-D (see Section 7.8.8) proved to be very potent as a growth regulator, and it was patented for that purpose in the early 1940s. But 2,4-D had one major disadvantage as a growth regulator: If dosages were too high, it killed the plants to which it was applied. At first, plant physiologists using these materials did not recognize this property as being useful, but during World War II the United States government began efforts toward finding chemical tools for destroying an

enemy's crops. It was during this period of secrecy that the weed-killing properties of 2,4-D were first recognized. The British reached the same conclusion regarding MCPA during the same period. Immediately after the war these phenoxy herbicides became highly publicized, and were widely used for the control of broadleaf weeds in grass crops. The impact on American and European agriculture was so dramatic that chemical companies immediately began searching for other chemical tools, and the modern age of herbicides had begun. A trickle of new herbicides quickly became a stream; until today 150 – 200 compounds worldwide are used commercially as herbicides. The dollar value of herbicides used in the United States now exceeds that of insecticides and fungicides combined.

Herbicide use has been controversial, particularly in the developed countries, since about the 1970s or 1980s. The use of any biologically active chemical carries risks, and there are considerable differences of opinion on how extensive and acceptable those risks are with respect to herbicides. With any method, the risks involved must be compared to the benefits obtained. Not surprisingly, many members of the public are less impressed with the potential benefits of herbicides than are vegetation managers.

Clearly, there are many advantages to using chemicals for weed control compared to other methods. It takes much less time to spray a field than to till it or hoe it. It may also be the least expensive method, especially when compared to hand-weeding. Many herbicides can damage the root system as well as the above-ground parts of weeds. It may actually be the only practical technique for controlling weeds that emerge with a solid-seeded crop, such as a small-grain crop, in which tillage is seldom practical and fields are too large for hand-weeding.

Nevertheless, benefits from herbicides must be balanced against the risks involved. Herbicides can drift from a target area and harm non-target plants. Some can persist in the soil and harm subsequent crops, be diverted to non-target areas, or enter the groundwater. They can be used carelessly, resulting in the denuding of a site, which may in turn lead to erosion, loss of wildlife cover, etc. Some herbicides are moderately toxic, and if used carelessly they can lead to inadvertent poisoning. The governments in most developed countries examine the potential risks and benefits of specific herbicides, regulate their registration, and monitor their use after introduction. This matter is discussed more thoroughly in Section 7.11 dealing with regulatory aspects.

7.2. Adjuvants

An adjuvant can be defined as "a substance added to a prescription to aid in the functioning of the main ingredient." Possible reasons for incorporating additives into a spray tank for pesticides include improved wetting, evaporation reduction, increased penetration, improved translocation, extended weatherability, retarded release, pH adjustment, enhanced deposition, compatibility, drift retardation, or odor inhibition. A few adjuvant types that are of particular importance for herbicides are discussed below.

7.2.1. Surfactants

Surfactant molecules are made up of a lipophilic portion and a hydrophilic portion. The lipophilic portion usually consists of long-chain hydrocarbons or benzenoid ring structures, which are very low in water solubility but high in oil solubility. The hydrophilic end has a high affinity for water.

The primary classes of surfactants are anionic, cationic, and nonionic based on the chemical structure of the hydrophilic portion of the molecule. An anionic surfactant ionizes in water to form a negatively charged hydrophilic portion; a cationic surfactant ionizes to form a positively charged hydrophilic part. These two types can be very useful for specific purposes, but they may also react with contaminants in a spray solution. For example, ionic-type surfactants might form insoluble precipitates in hard water. Most of the commonly used agricultural surfactants are nonionic. These are easy to use, nontoxic, and unaffected by hard water. An example of each type of surfactant is given in the following:

Anionic:	sodium stearate $C_{17}H_{35}COO^{-}Na^{+}$
Cationic:	cetyltrimethylammonium bromide $C_{16}H_{33}(CH_3)_2N^{+}Br^{-}$
Nonionic:	poly(ethylene oxide) lauryl alcohol $C_{12}H_{25}O(CH_2CH_2O)_{23}H$

A newer form of nonionic surfactant is the silicone type, an example of which is shown here:

Specific surfactants can be used in many ways, including as wetting agents, dispersing agents, emulsifiers, foaming agents, detergents, etc. Some of these uses are primarily related to the formulation of a commercial product, as discussed in Section 7.3.

A wetting agent is added to herbicides to cause spray droplets to spread over the surface of the leaves, thus increasing coverage and eventual uptake of the herbicide. All the details of the process are not yet well understood, although it is known that maximum reduction of spray-droplet surface tension can usually be achieved with a wetting agent concentration of less than 0.1 %. This means that increasing the surfactant content will not cause the spray droplet to spread out any farther. But it is also known that both uptake and effectiveness of many herbicides continue to increase as the wetting agent concentration is increased above 0.1 %. This must mean that there are other ways in which a surfactant improves herbicide uptake besides simply reducing the surface tension of the spray solution.

Intensive research with surfactants has usually shown that a particular surfactant is ideal for a specific herbicide on a particular species. This of course greatly complicates the problems involved in making recommendations for herbicides that might be used on a wide range of weed species. As a result, recommendations usually refer to a small number of common surfactants shown to be reasonably effective over a wide range of herbicides and species. Household detergents are designed for an entirely different purpose, and are usually considerably less effective as adjuvants for herbicide sprays.

Increasingly popular are formulations containing phytobland oils and a significant concentration of surfactant (generally 4 – 10 %). These products are more effective in improving herbicide retention and uptake than surfactants alone. Some herbicide labels actually specify their use, usually at a rate of about 2 L/ha.

7.2.2. Oils

Oils have been used in herbicide sprays for many years. Such oils can be divided into three types:

1) Phytotoxic, nonselective: These are heavy oils with a high degree of unsaturation (i.e., many double and triple bonds and aromatic groups). The high degree of unsaturation makes the molecules readily subject to sulfonation, hence giving them a low unsulfonatable residue (USR) rating. Oils in this category are generally added to knockdown-type herbicides for road spraying or canal and ditchbank spraying, or to brush killers to facilitate uptake through the bark. Diesel fuel is an example.
2) Phytotoxic, selective: These oils are not actually adjuvants because they may be sprayed directly, without mixing with water or combination with herbicides. They are intermediate in terms of viscosity and percent USR, and are used mostly for broadleaf weed control in certain crops such as those of the carrot family. The carrot family apparently is better able to withstand the effects of oil on their membrane systems than most common weeds, so the crop plant is not harmed even though the weeds are controlled.
3) Phytobland oil – water emulsions: These are light oils that are nearly saturated chemically, and thus have a high %-USR. The oils themselves are not phytotoxic, but are often added to herbicides that require help in penetrating plant leaves. They are sometimes called corn oils, superior spray oils, supreme spray oils, and other common names.

7.2.3. Drift Retardants

When a spray solution is atomized by being forced through a spray orifice under pressure, a large number of extremely fine spray droplets accompany the normal-size droplets. These "fines" can easily be diverted from the target area with even a slight breeze. If the herbicide is sufficiently phytotoxic, if the breeze is sufficiently strong, or if the numbers of fines produced by the spraying operation is sufficiently large, serious damage to non-target species can result. For this

reason, several products have been developed to reduce the number of fines, thus reducing drift. These are mostly long-chain polymers, such as anionic polyacrylamide. Most such products can simply be added to the spray tank, and do not require any special application equipment. Care must be taken to ensure that the resulting change in character of the spray solution does not result in increased damage to the sprayed crop.

7.2.4. Other Adjuvants

Foaming agents are most often used as a way of generating a glob of foam at either end of the spray boom to serve as a marker.

An emetic causes immediate vomiting to reduce the hazard of accidental ingestion.

A stenching agent is sometimes added to the more toxic products to help prevent a pesticide from being mistaken for a soft drink, etc.

7.3. Herbicide Formulations

Once a commercial pesticide has been selected a decision must be made about which formulation will be used. There may be several available formulations for any given product. In this case, proper formulation selection can mean the difference between failure and success. Proper handling and application varies from one type of formulation to another. Therefore, it is essential that the operator have a basic knowledge of pesticide formulations.

In general, formulating means preparing a product for practical use. The formulation can influence the accuracy of application, the effectiveness of pest control in a particular situation, the selectivity of certain pesticides, convenience to the operator, and, very importantly, the cost of the treatment.

Pesticides are applied mainly as sprays or as dry materials such as granules or pellets. Some fumigants such as bromomethane are applied in gaseous form. Spray formulations include water solutions, oil-soluble liquids, soluble powders, emulsifiable concentrates, flowable formulations, wettable powders, dispersible granules or dry flowables (two designations for the same thing), invert emulsions, and encapsulated formulations. Dry materials are formulated as granules, dusts, or water-soluble pellets.

Many factors must be considered in deciding how to formulate a specific active ingredient. These can include:

1) Chemical and physical properties of the pesticide: The solubility of the pesticide in various solvents is of major importance, as will be discussed later. The volatility of the material may also dictate the preferred type of formulation.
2) Intended use: If a herbicide is intended for use in a foliar or bark application for control of waxy or brushy species it will likely be part of some type of oily formulation, whereas if it is intended as a selective treatment it is more likely to be formulated with less oil and less wetting agents. If designed to control small weeds in a growing crop through soil activity it may be formulated as granules to allow it to filter through the foliage canopy and reach the soil.
3) Geographical area of use: The customs of growers differ in various parts of the world. Many farmers own granular spreaders, and have beome accustomed to using granular products, whereas in more arid areas granules tend to be less consistent in performance, and are less readily accepted by growers.
4) Materials available for formulation: Some manufactures have switched formulations simply due to a lack of particular solvents, emulsifiers, or containers.
5) Economics: An economic analysis could include several of the factors cited above. The cost of formulating agents and containers as well as relative shipping costs and other factors must all be considered. In general, formulations with a low percentage of active ingredient (such as granules) are most expensive to the grower. Large increases in the costs of solvents and emulsifiers in recent years has changed the economic picture relative to emulsifiable concentrates. The relative cost of formulation may not be of major importance with certain high-value crops, but in other crops the cost of the product will be crucial for acceptance on the part of the grower.
6) Convenience: Some formulations are easier to measure, result in fewer dust problems,

come in more readily disposable containers, etc., and these factors may also influence acceptability in the marketplace.

7.3.1. Spray Formulations

7.3.1.1. Soluble Concentrates

With products of this type the active ingredient can be dissolved readily in either water or oil to form a true solution. In the case of a water-soluble pesticide the manufacturer may dissolve the material in a small amount of water and sell the product as a concentrate for further dilution by the user. In general, such a pesticide should be soluble at least to the extent of 10 % in water in order to be suitable for distribution as a liquid concentrate.

The manufacturer may alternatively choose to sell a water-soluble pesticide as a dry powder for mixing with water by the user. Usually the content of active ingredient ranges from 50 – 80 %, the remainder being adjuvants and diluent.

Adjuvants may be added to water-soluble products to improve their application and effectiveness. Wetting agents are commonly incorporated, and sequestering agents are sometimes added to prevent precipitation in hard water.

Major advantages of water-soluble pesticides are relatively low cost of formulation and the fact that no agitation is required in the spray tank once the materials have been thoroughly dissolved. Problems that may arise from the use of soluble pesticide formulations are as follows:

1) They may react with hard water, causing clogging of the spray equipment or rendering the pesticide nontoxic.
2) The active ingredient may not enter the plant foliage readily, due perhaps to the excessive surface tension of water, which may leave pesticide crystals on the foliage. This actually may be a desirable characteristic when selectivity of the compound is based upon differential wetting, but it would be undesirable if the goal is nonselective treatment, or if the weeds being treated are waxy.
3) The chemical may be readily leached through the soil by water. This can be an advantage when applying a herbicide to control deep-rooted perennial weeds; however, with selective pre-emergence herbicides it can be an undesirable property because the herbicide is subject to leaching by excess rain or irrigation, resulting in only a brief residual control, ineffective performance, or injury to the crop.

7.3.1.2. Emulsifiable Concentrates

Some pesticides cannot be directly dissolved in water. However, they may be soluble in a nonpolar organic solvent such as xylene, which can be mixed with water to form an emulsion.

An emulsifiable concentrate consists of a nonpolar solvent in which the pesticide is dissolved, together with an emulsifying agent. When an emulsifiable concentrate (EC) is added to water in a spray tank, a stable emulsion is formed. Tiny solvent droplets are dispersed throughout the water carrier, with each solvent droplet containing some of the dissolved pesticide. Thus, the pesticide is not dissolved in the water, it is simply suspended in the water while remaining dissolved in the nonpolar solvent. The emulsifying agent keeps the solvent droplets dispersed. Hundreds of emulsifiable concentrates are available on the market.

Formulating a pesticide as an emulsifiable concentrate requires that the active ingredient display adequate solubility in nonpolar solvents. A solubility of at least 10 % is required for preparing a cost-effective EC. Most ECs contain at least 25 % active ingredient, and a few contain as much as 0.9 kg/L.

An EC penetrates the waxy foliage of leaves better than other formulations. This means that it may be more effective against hard-to-kill weeds, but also less selective than other formulations. ECs can be applied in hard water without adverse reactions, and they are less likely to be washed off the foliage by rain or sprinkler irrigation. They are less abrasive to pumps and sprayer parts than are wettable powders, and they remain suspended in the tank for longer periods of time than wettable powders. However, the user must remember that the emulsion in the spray tank is still a suspension, and that some agitation is required to preserve its emulsion character.

Emulsifiable concentrates and emulsions are more easily absorbed by the skin than wettable

powders and dusts, and are thus more hazardous if spilled or splashed on the operator.

7.3.1.3. Wettable Powders

Some new pesticides are insoluble in water and insufficiently soluble in organic solvents to permit EC formulation. In that case, the material can be ground very finely and formulated as a wettable powder (WP). A WP is defined as a powder that will readily form a suspension in water.

Wettable powders are formulated by impregnating the active pesticide on an inert material such as clay. A wetting agent and a dispersing agent are also added to the formulation. The wetting agent helps wet the pesticide itself upon addition to water, preventing the material from simply floating on the surface. A dispersing agent aids in spreading the individual particles throughout the water. A typical 50 % WP may contain 42 % clay, 2 % wetting agent, 2 % dispersing agent, and 4 % other impurities (inert ingredients) along with 50 % active pesticide (active ingredient).

Since wettable powders are suspensions and not true solutions, considerable agitation is necessary to prevent settling out. An analogy would be silt carried along by a river. As long as the water remains turbulent, the materials stay suspended. Wettable powders generally have less foliar activity than other types of spray formulations. In fact, some herbicides have been explicitly formulated as WPs even though they could also be formulated as ECs because WPs generally cause less injury to the crop (and sometimes cost less as well). When applied to the soil they generally require activation by rain or sprinkler irrigation. They tend to be abrasive on pumps and nozzle tips of spray equipment. Since they generally contain a rather high percentage of active ingredient, and no solvents or metal containers are needed, the cost per unit of active ingredient tends to be lower than with many other formulations.

Some wettable powders are sold in water-soluble bags, which are then simply introduced into the spray tank. This can be useful when (1) the required application rate is very low, making weighing difficult, or (2) some toxicological question has been raised, since the bag allows the user to avoid all contact with the herbicide.

Wettable powders should be mixed with a small amount of water to form a slurry before mixing with the water in a spray tank. This helps disperse it in the water, and assures that a maximum amount of active pesticide will remain in suspension.

7.3.1.4. Flowables

Flowable formulations are concentrates of liquid or solid pesticides, suspended in a liquid. The most common flowables on the market contain very finely ground pesticides in the form of powders suspended in water. In some respects, such a formulation might be regarded as a prepackaged slurry ready for addition to the spray tank. Since this formulation is a suspension and not a solution, thorough agitation of the container is required before the material is measured out.

7.3.1.5. Dispersible Granules or Dry Flowables

This relatively recent type of formulation is becoming increasingly popular. The two names "dispersible granules" and "dry flowable" refer to the same thing. Such a formulation consists of small beads that disperse into a suspension when added to water. The spray mixture must be agitated, just as in the case of wettable powders. The dispersible granules create no dust problem and they can be measured by volume as well as by weight. A graduated cylinder is included with some products for accurate measurement. Some difficulties have been encountered in mixing certain dry flowables with liquid fertilizer. One should try suspending the formulation in water first before mixing it with a liquid fertilizer. This is conveniently accomplished by working with appropriate concentrations in a 1-L jar prior to mixing up a whole tankful.

Some herbicides applied at very low dosages per unit area are formulated as effervescent tablets that can be counted out and tossed into the spray tank. These quickly become dispersed, and essentially function like a wettable powder or dispersible granules.

7.3.1.6. Invert Emulsions

An invert emulsion is one in which water is the discontinuous phase and oil is the continuous phase. This results in a thick mayonnaise-like product. The primary reason for formulating an invert emulsion is to reduce drift from airplane applications or handgun applications along roadsides and railroads. Special emulsifiers are required to create an invert emulsion, and special equipment is needed for its application.

7.3.1.7. Encapsulated Formulations

New methods have been developed to trap small amounts of pesticide in tiny capsules, which are then suspended in a liquid. Such a concentrate can be mixed with water and applied through a regular sprayer. One purpose of encapsulating pesticides is to facilitate controlled release of the material over a period of time in order to prevent excessive loss by evaporation or from extensive leaching. Also, a formulation of this type may have less tendency to adhere to plant residues on the soil surface.

Poly(vinyl chlorides) and other plastics are being studied as slow release agents for pesticides. The pesticide is mixed with the plastic while the latter is still in liquid form. As the plastic hardens, the pesticide is trapped in tiny compartments, to be released slowly as the plastic breaks down. Mixtures containing such slow release materials as starch are under development.

7.3.2. Formulations Applied Dry

Granules. Granular formulations contain 2 – 20 % concentrations of pesticide in particulate solid carriers suitable for direct field application. They are prepared by impregnating the pesticide on inert particles such as clays, or on such botanical materials as ground corn cob or walnut shells. The particles are screened so that the majority usually fall between 15 and 40 mesh (6 to 15 wires per linear cm).

Granules may be applied with less expensive equipment than sprays, and their application is more convenient. They are able to penetrate a plant canopy, and reach the soil easily. They may also release pesticides gradually over a period of time, which can be advantageous in certain cases. Furthermore, there is less drift hazard with granules, and it is not necessary that the pesticide be soluble in either water or nonpolar solvents for formulation as granules. The cost of granules per unit of active ingredient tends to be higher than with other formulations. There is also a greater chance of poor distribution on the soil than with sprays, since granules may roll or blow from the tops of ridges into furrows, for example. Some pesticides that require greater amounts of water for activation in the soil may be less effective when applied in granular form.

Pellets. Pellet formulations contain larger particles than granules, and are basically used for spot treatment. Many pellets are formulated in water-soluble materials such as borates rather than the insoluble inert materials used with granules. They have most of the same advantages and disadvantages as granular formulations.

Dusts. Dusts usually contain only two ingredients, an inert diluent, usually a clay, and the toxicant. The latter rarely accounts for more than 10 % of the weight of the mixture, and is more often about 1 %. For this reason dusts are more costly per pound of toxicant (because of shipping costs). Herbicides are seldom, if ever, sold as dusts because dusts drift readily.

7.3.3. Active Ingredient vs. Acid Equivalent

Two technical terms need to be discussed at this point. *Active ingredients* refers to those chemicals in a product that are responsible for the pesticidal effects. In a dry formulation, the active-ingredient content is expressed as a percentage by weight. A wettable powder may contain 80 % active ingredient, and a granular product may contain 4 % active ingredient, for example. The concentration of a pesticide whose active form is an acid is usually expressed as an *acid equivalent*. This refers to the theoretical yield of parent acid from the true active ingredient present. Thus, a particular herbicide such as 2,4-D may be active only in the acid form, but for various reasons the acid may have been changed into a salt or an ester. The ester or salt is regarded

as the active ingredient, but dosage recommendations are based on the number of molecules of acid per hectare, whether in the acid, salt, or ester form (Fig. 7). In other words, it woud be expressed as "1 kg of 2,4-D acid per hectare" rather than "1 kg of 2,4-D ester per hectare." A molecule of 2,4-D ester might of course be considerably heavier than one molecule of 2,4-D acid, so a dosage of 1 kg of active ingredient per hectare would release considerably fewer molecules than a dosage of 1 kg of acid equivalent. To avoid confusion, everything is converted to a weight in terms of acid rather than considering a total true weight of active ingredient.

Figure 7. Everything within the solid line is active ingredient. Everything within the dotted line is acid equivalent. The acid equivalent may be identical, but the active ingredient of the ester is higher (heavier total molecule).

7.4. Factors Influencing Foliage-Applied Herbicides

For a foliage-applied herbicide to be effective, the following chain of events must be successfully accomplished: the herbicide must (1) reach the plant, (2) be retained on the leaf, (3) penetrate the leaf, (4) move to its site of action, and (5) remain toxic long enough to exert its action.

Reaching the plant seems an obvious requirement for effective herbicide use. However, this is often overlooked in practical field situations. There are at least three ways in which proper amounts of herbicides fail to reach the leaves.

One of these involves spray drift, which is the lateral movement of spray particles, including the carrier. In general, large nozzles and low pressure will reduce spray drift, because larger spray droplets are formed. Also, drift retardants may be added to a spray solution.

Volatilization of a material prior to reaching the plant is another possibility, particularly with aerial applications. This refers to a change in the herbicide from the solid or liquid state into the gaseous form. Several herbicides are sufficiently volatile that significant percentages could be lost in this way. At this point it is important to stress the difference between spray drift and volatility. Volatility refers to a change to a gas, whereas spray drift implies the movement of spray droplets. Some people attempt to disclaim any responsibility for damage caused by spray drift on the grounds that they have used a nonvolatile formulation, but this is not a compelling argument, because even nonvolatile materials can drift.

A third way in which a herbicide might be prevented from reaching the target leaf would be shading from taller plants. This is generally referred to as the "canopy" effect. Complaints are commonly lodged that a particular contact herbicide has failed to work properly because there are many surviving plants. Often this is a result of the fact that the herbicide contacted only the top overlying layer of leaf surfaces, and failed to reach the smaller plants underneath.

Figure 8. Leaf arrangement and type can influence retention

Once a herbicide reaches the leaf, it must be retained on the surface long enough to be absorbed. Several factors can be involved in retention. The morphology of the plant has a considerable effect. Whether the leaves are upright or horizontal might determine whether or not spray droplets would remain on the leaf or run off (Fig. 8). Also, retention may depend on whether the leaf is waxy or nonwaxy. Extreme exam-

ples are wild garlic and mustard. Wild garlic has waxy, upright leaves, while mustard has broad, horizontal, nonwaxy leaves.

The characteristics of the spray solution are important as well. These can be altered by the inclusion of additives or adjuvants, such as adhesives or "stickers." Wetting agents often act as sticking agents when applied in small volumes of water. For example, the use of wetting agents is always recommended with paraquat on grasses. Otherwise, retention on the leaves is poor.

The volatility of the herbicide also may be important. Some materials evaporate too rapidly to provide adequate retention time.

Herbicides can enter the leaves through either the lower or upper leaf surfaces. Usually the lower surfaces are more permeable than the upper sides. The herbicide can penetrate the leaf either through the stomates or directly through the cuticle. The relative importance of each of these routes is open to debate, but it almost certainly depends upon the particular species involved and the environmental conditions (light, humidity, and whether the stomates are open or closed). Other relevant factors include the nature of the herbicide, its formulation, etc. Most authorities agree that although stomatal uptake can be important, cuticular uptake is of most vital concern. The discussion that follows will focus primarily on cuticle uptake, but it must be remembered that uptake can also occur through the stomates.

Assuming that a herbicide is retained on the leaf, at least four things might happen to it.

1) It can remain on the outside, either as a crystal or a liquid. This can occur with many salts when the aqueous carrier evaporates rapidly.
2) It can enter the cuticle and remain dissolved in the nonpolar portion. This can happen with various weed oils.
3) It can enter and move in the aqueous phase along the cell walls to the vascular system. An example showing this behavior is amitrole.
4) It could enter and move directly into living cells, and through them to the vascular system. The best example of this mode of transport would be 2,4-D.

Nature of the Leaf Cuticle. It is important to understand something about the composition and structure of a leaf cuticle. The leaf cuticle is a complex layer that covers the outside of a leaf. It constitutes a barrier to water loss from the leaves in dry weather, but it also presents a barrier to the penetration of applied herbicides. The constituents of a typical plant cuticle are as follows:

Cutin waxes – nonpolar, lipophilic. Short-chain esters and alcohols of relatively low molecular mass and lacking reactive end groups; some may be cyclic in nature.

Figure 9. Hypothetical structure of a cuticular layer

Cutin – partly hydrophilic and partly lipophilic. Polymerized acids and alcohols of high molecular mass, and also characterized by reactive end groups.

Pectins – amorphous and highly hydrophilic. Made up of polyuronides.

Cellulose – hydrophilic, fibrillar in nature. Permeable to water and polar in nature.

Aqueous and Lipoidal Routes of Uptake. Polar water-soluble herbicides follow a different route through the cuticle than nonpolar herbicides. The cutin waxes are quite lipophilic in nature, and are difficult for water-soluble herbicides to penetrate. Penetration thus depends upon cracks, insect punctures, etc. A water-soluble herbicide then traverses the hydrophilic part of the cutin, avoiding the suspended wax platelets shown in Figure 9. When it reaches the pectin and cellulose, its progress is much easier, because these materials are hydrophilic and generally quite aqueous in nature. This pathways has

been termed the aqueous route. Nonpolar herbicides follow a lipoidal route. Because these materials are lipophilic in nature, they can easily penetrate the waxy barrier and move through the lipophilic portions of the waxes and cutin. If a herbicide is too lipophilic in nature, however, it may have a difficult time penetrating the hydrophilic pectin and cellulose, and will partition instead into the waxes, thus inhibiting uptake. Esters may hydrolyze to the more water-soluble acids and thereby move into the hydrophilic areas.

Environmental conditions can drastically affect the uptake of herbicides, particularly those that are water soluble. When relative humidity is high, spray droplets evaporate less rapidly, allowing more time for the dissolved herbicides to penetrate. Also, the hydrophilic portions of the cutin and pectin strands can absorb moisture and become swollen. This forces the wax platelets farther apart and provides a much easier route for the water-soluble herbicides to penetrate. Relative humidity has less effect on nonpolar, lipophilic-type herbicides.

In summary, important points regarding cuticular absorption are as follows:

1) The existence of both aqeuous and lipoidal access routes
2) Cuticles are thicker when developed under dry conditions, thinner under wet conditions, as illustrated by the extremes of cactus and aquatic plants; this can influence uptake of foliar-applied herbicides
3) Uptake can be affected by chemical properties of herbicides, e.g., polar vs. nonpolar, water solubility, etc.
4) Formulation is important; emulsifiable concentrates are more readily absorbed than wettable powders, etc.
5) Adjuvants, such as wetting agents and penetrants, can increase uptake, particularly of polar materials
6) High humidity conditions can increase uptake, especially of polar materials by
   a) Reducing evaporation of carrier from the leaf surface
   b) Moisture absorption by hydrophilic substances in the cuticular layer (hydrophilic parts of cutin and strands of pectin), causing it to swell and making the aqueous route more favorable, a swelling which also forces the wax platelets farther apart

Translocation in plants involves two different systems – the phloem and the xylem (Fig. 10). Some foliage-applied herbicides are considered contact-type materials; i.e., they kill only that tissue with which they come in contact. However, many important herbicides can move from the point of application on the foliage to other parts of the plant. Systemic herbicides of this type include such compounds as 2,4-D, amitrole, glyphosate, and many others.

Figure 10. Herbicide transport in the phloem and xylem systems

An important concept with respect to translocation centers around the symplast and the apoplast. The symplast refers to the total interconnected protoplasm of all plant cells, functioning as a unit. This includes phloem, living cells, and the plasmodesmata (strands of protoplasm connecting living cells). The apoplast consists of nonliving tissues together with water surrounding the symplast. This includes the xylem and the secondary walls. Herbicides can move short distances by simple diffusion, but for true systemic action they must move in either the xylem or the phloem.

The movement of herbicides in the symplast has become much better understood in recent years. Movement of solutes in the phloem seems

to occur by a "mass flow" mechanism. Sugars are actively loaded into phloem cells in the leaves through the expenditure of energy from ATP. This increases the osmotic pressure, causing water to pass into those cells, leading to what is called the "source." At the "sinks" sugars are unloaded for metabolism or storage purposes, causing the osmotic potential to fall. Therefore, water simply moves from the source to the sink hydrostatically, like water through a hose. Herbicides seem to diffuse into the phloem in the leaves, permitting them to be carried along with the water to the sink.

The mechanism of herbicide movement has been studied extensively. Some herbicides, such as atrazine, seem not to move in the phloem. Yet, it is known that atrazine is fully capable of entering living cells, so why does it not move in the phloem? Recent information indicates that atrazine can move through cell membranes almost without resistance. Likewise, it can diffuse back out just as easily. Because the xylem stream is more voluminous and swift than the phloem stream, atrazine (and other such herbicides) is simply swept upward in the xylem at the expense of moving downward in the slower phloem stream.

A high percentage of the herbicide load moving in the phloem seems to be acidic. The pH outside the phloem is lower (i.e., 5 – 5.5) than inside the phloem (7.5 – 8). More of the acidic components are in the acid form at pH 5, causing them to be more lipophilic and thus able to diffuse through the cell membrane into the phloem. Once inside the phloem they tend to dissociate into the anionic form at the higher pH that prevails there, thus becoming less lipophilic (Fig. 11). In other words they become "trapped" inside the phloem, and much less able to escape than atrazine and similar substances, which means they are carried along with the water and sugar in the phloem. This mechanism does not explain the phloem movement of certain herbicides, however, such as glyphosate, that do not change form between pH 5 and pH 8. Glyphosate is able to penetrate the membrane into the phloem only with great difficulty, and therefore it also diffuses out only with difficulty, so it simply moves along with the phloem stream and does not escape into the xylem. This represents an illustration of the "intermediate permeability" hypothesis.

Figure 11. "Trapping" of weak acids in the phloem
The acid form can diffuse through the plasmalemma. Inside the sieve element, the high pH causes more of the acid to ionize. The more polar ion is much less lipophilic than the acid, and cannot diffuse back through the lipophilic plasmalemma as readily, thus trapping it inside where water movement carries it to the sink

There can be varying degrees of partitioning between the symplast and the apoplast. Some herbicides seem to move entirely in one or the other, but others are able to move in both types of tissue. Several compounds – including dicamba and picloram – can move from the foliage in the symplast, along with sugars, or else upward in the xylem.

In annual weeds, herbicide translocation over long distances is generally not of major importance compared to other factors influencing effectiveness. With many species of biennials it is critical that treatment occur at the seedling stage or in the rosette stage, but before the plant sends up a flower stalk, whereas in perennials, the source-to-sink concept can be of major importance in the timing of spray application. In a plant newly emerged from vegetative parts, most of the sugar produced in the leaves is necessarily used to form new vegetative growth, and more is supplied from root reserves; i.e., sugar movement is mostly upward, and spraying should be delayed (Fig. 12). When the plant reaches the bud or early bloom stage, vegetative growth slows down or ceases entirely, and most of the sugar produced in the leaves begins to move toward underground storage tissue. Application of herbicides at this point is often most effective for long-term control, because source-to-sink movement results in more complete translocation throughout the plant.

Figure 12. Carbohydrate movement in perennial weeds A) Newly emerged; B) Vegetative growth; C) Bud or bloom-stage

The other season during which downward sugar movement occurs rapidly is in the fall, when perennial plants are storing root reserves for the winter.

Most translocation of herbicides from the leaves occurs in the phloem. Since such translocation depends upon living tissue, rapid burning of the leaves and stems can be detrimental to good translocation, and would be a case of "burning your bridges in front of you." therefore, application to perennial weeds of the most toxic formulation available of a translocated material should be avoided, because it would kill the tops of the plants too quickly for good distribution into the roots.

7.5. Factors Influencing Soil-Applied Herbicides

Many herbicides now available on the market are intended for application to the soil for uptake by emerging shoots or the roots of weeds. Unlike leaves, roots are highly adapted as absorbing organs, and they are very effective at taking up herbicides. Nevertheless, soil-applied herbicides are not always available for uptake into the plant. The issue is one of availability as the major factor influencing the effectiveness of soil-applied herbicides.

7.5.1. Microbiological Effects

Before examining the effects of microbes on herbicides it is appropriate to mention briefly the effect of herbicides on microbes in the soil. This is an issue that has not been completely resolved. Most studies show that normal rates of herbicide application sometimes cause a temporary shift in the microbe population, but seldom an overall reduction. Any such reductions are usually very temporary. Changing the kinds of microbes available in the soil could have a considerable effect, and it is worthy of more thorough investigation, but so far very little detrimental influence of this type has been noted.

Microbes are able to use herbicides for food. They also have the ability to break down a herbicide rather incidentally, perhaps while working on another food source. At any rate, the breakdown of herbicides in soils by microbes is a very important phenomenon. Without microbes, most herbicides would remain in the soil indefinitely, and perhaps cause serious problems by persisting from one year to the next.

Some herbicides are decomposed very rapidly (i.e., within three to four weeks). This includes such compounds as 2,4-D and EPTC. Other compounds are more resistant to microbial breakdown, and can persist even more than one year, including such herbicides as diuron and atrazine.

In general, any condition favorable to the growth of microbes will hasten herbicide decomposition. Temperature, moisture, aeration, organic-matter content, pH, minerals present, concentration of the herbicide, species of microbes present, the particular herbicide involved, and preconditioning (soil enrichment) can all be important factors. A warm, moist, fertile soil is generally ideal for herbicide breakdown, but these conditions are not always met. In many arid regions herbicides are applied to the surface of furrow-irrigated fields. Unless rainfall occurs, the herbicide remains on the dry surface of the soil. Microbes obviously are not active under such circumstances, and the herbicide not only fails to provide good weed control but may persist until the next season and cause crop damage. Even if the herbicide is incorporated into the soil, the upward movement of furrow-applied water may bring it to the surface (Fig. 13).

Figure 13. Upward movement of water often forces herbicides to the soil surface in furrow-irrigated fields

Adaptive Breakdown. Particular strains of microbes that can use a herbicide for food may gain an advantage over other microbes in the soil, and therefore increase rapidly in numbers. As the numbers of this particular type of microbe increase, the herbicide is broken down more and more rapidly. This increase in microbe population is sometimes termed "soil enrichment," although obviously has nothing to do with soil fertility. When a herbicide is first applied to a soil, initial breakdown usually is slow, but as herbicide-consuming microbes proliferate, breakdown occurs much more rapidly. The initial period is called the "lag phase," as illustrated in Figure 14. If the same herbicide is reapplied to the same soil after the first application has disappeared, breakdown will occur much more rapidly, and the lag phase may be eliminated completely. This is of course because the microbe population has already been built up, and it is ready to attack the herbicide at once. Some few thiocarbamate herbicides such as EPTC and vernolate have become much less effective in certain "problem" soils because of the soil enrichment phenomenon.

Figure 14. Adaptive breakdown of soil-applied herbicides by microbes

Incidental Breakdown. Many herbicides are subject to degradation by microbes despite the fact that the microbes appear not to be favored in any way. These herbicides simply seem to "get in the way," and they are degraded incidentally as the microbes ingest other materials. The microbe population does not increase, and there is no lag phase, and thus no soil enrichment. Herbicides that undergo this type of microbial breakdown tend to be more persistent in the soil than those broken down by the adaptive mechanism. These include the ureas, triazines, uracils, sulfonylureas, and many miscellaneous herbicides.

7.5.2. Adsorption on Soil Colloids

Adsorption (not *absorption*) is a very important process with respect to soil-applied herbicides. Adsorption refers to the chemical and/or physical attraction of a substance to a surface. When a herbicide is applied to a soil, a considerable fraction of it can become attached so firmly to the soil colloids that the molecules are unavailable for uptake by plants. This is an equilibrium process, and as herbicides are removed from the surrounding soil solution, more herbicide will be desorbed and dispersed in the solution (Fig. 15).

Figure 15. Equilibrium process of herbicide adsorption on soil

The extent of herbicide adsorption depends heavily on the nature of the particular herbicide in question. Some herbicides are quickly and firmly adsorbed (paraquat), while others are adsorbed to a much lower extent (sodium chlorate).

There are four primary soil factors that can affect the extent of adsorption:

1) Texture (sand vs. clay): Texture influences the extent of adsorption by affecting the surface area available. Clay particles are much smaller than sand particles, so the available surface area per unit of volume is much greater in a clay soil than in a sandy soil. Therefore, herbicides are adsorbed to a greater extent in clays than in sands, and higher application rates are necessary in clay soils to ensure adequate activity.
2) Type of clay: Clays vary greatly with respect to exchange capacity. Montmorillonite clays have greater exchange capacity, and can adsorb larger amounts of herbicide, than illite or kaolinite.

3) Organic-matter content: This is perhaps the most important soil factor affecting herbicide adsorption, probably more important than texture in determining the amount of adsorption. Some soils are very high in organic matter, such as muck soils or areas around sawmills, and these have such a tremendous adsorptive capacity that soil-applied herbicides are seldom effective. At the other extreme, some desert soils have an organic matter content $< 1\,\%$, and great care must be exercised to prevent crop damage, because applied herbicides are extremely effective.
4) Soil moisture: It is now known that water can compete with herbicides for adsorptive sites on soil colloids (Fig. 16). In the case of volatile materials applied to the soil surface, loss is much greater from a moist soil than from a dry soil. Volatile herbicide can be adsorbed more quickly and more completely on dry soil, resulting in little loss into the atmosphere, whereas on wet soil the water inhibits adsorption, and herbicide loss is extensive. On the other hand, some herbicides tend to be adsorbed too much for optimum activity, and if they are not volatile it may be desirable that adsorption be minimized. Application of many nonvolatile herbicides is more effective if delayed until after the soil has been moistened by rainfall. The principles are the same in both cases; the goal in one case is simply adequate adsorption with slow release, but less adsorption in the other case.

Figure 16. Water can compete with herbicides for adsorption sites

7.5.3. Chemical Decomposition

Several chemical reactions common in the soil are capable of breaking a herbicide down. These can occur even in sterile soils where microbes are not a factor. Relevant chemical reactions include oxidation, reduction, hydrolysis, and hydration. The first inactivation step with chloro-*s*-triazines has been shown to be a nonmicrobial hydrolysis, with loss of the chlorine atom. Sulfonylureas are degraded both by hydrolysis and by microbial action, and it proceeds much more slowly in high-pH soils (> ca. 7.8).

7.5.4. Leaching

Leaching refers to the downward movement through the soil of a substance in solution. The extent of herbicide leaching through a soil depends on its solubility, the volume of water passing through the soil, the distribution of the water, and the adsorptive relationships between the herbicide and the soil. In general, some movement of the chemical is always required in order to ensure that it will pass into the soil where it can be absorbed by weed roots. However, it is usually not desirable that the herbicide move too deeply, because it would then be ineffective on the weeds, or injurious to deep-rooted crops.

7.5.5. Volatilization

Some herbicides are subject to evaporation and loss in the form of a gas or vapor, including such compounds as EPTC, metham, cycloate, trifluralin, dichlobenil, and others. Such materials must usually be incorporated mechanically into the soil soon after application. Some herbicides that are less volatile can still evaporate over a period of time if the environmental conditions are hot and dry. Examples include 2,4-D high-volatile esters and even atrazine.

7.5.6. Photodecomposition

Herbicide molecules lying on the soil surface may absorb light and then be incapable of releasing the resulting energy. In this case, the energy causes chemical bonds in the molecule to rupture, and the herbicide is destroyed. Most herbicides are not highly susceptible to photodecomposition, but it can occur over a period of time. Urea herbicides such as diuron are known to be broken down by light when they remain on the soil surface for several weeks. Trifluralin, paraquat, and napropamide are other herbicides

known to photodecompose. Napropamide especially must be incorporated quickly for satisfactory activity. Movement into the soil induced by rainfall or irrigation helps prevent this photodecomposition.

7.5.7. Uptake and Translocation from the Soil

Soil-applied herbicides are naturally expected to be taken up by the roots of weeds. However, several important herbicide groups (including the thiocarbamates, dinitrobenzene amines, acetanilides, and DCPA) are effective on grasses as a result of uptake into the emerging shoot (see also Section 7.6). Some, such as the thiocarbamates, show almost no toxicity when only the roots are exposed. Others, such as the dinitrobenzenamines, are able to cause severe damage to roots, but because weeds can survive drastic reductions in root growth, the primary lethal action occurs through uptake into the emerging shoot. Shoot-uptake herbicides seem not to be translocated significantly.

Herbicides that are effective through the roots – ureas, triazines, uracils – move to the foliage in the xylem. Herbicide movement in the xylem seems to be completely passive; i.e., the herbicides simply go where the water goes, when the water goes, and to the extent that the water goes. It is analogous to a wood chip in a river; there is no particular control, and movement is dictated completely by the streaming water. This means that conditions of high transpiration (i.e., high soil moisture and low relative humidity in the air) favor rapid herbicide uptake from the soil. Herbicides also can move in the apoplast subsequent to foliar treatment. This results in concentration at the tips and edges of the leaves, and of course does not result in movement to the roots.

The soil is a complex medium. Many of the factors discussed above can interact one with another (Fig. 17). Any one factor can be sufficiently important to lead to the success or failure of a herbicide application. Of all environmental factors, soil moisture is likely to be the key factor in a successful treatment. Poor moisture conditions probably cause more failures with soil-applied herbicides than any other single problem. Growers with access to sprinkler irrigation have a considerable advantage when it comes to the use of soil-applied herbicides because they are able to assure that the compound will be leached from the soil surface into the weed uptake zone for optimum control. A herbicide lying on the soil surface, unless it is a volatile compound, simply cannot do a satisfactory job of controlling germinating weeds. Even if a herbicide has been mechanically incorporated into the soil, in the absence of sufficient moisture it may not be available for uptake. Weed seedlings emerging from deeper, moist soil can emerge through the dry soil layer unharmed. Proper placement in the soil and adequate moisture are critical concerns.

7.6. Selective Action of Herbicides

Selectivity is the result of a chemical reaching and disrupting a vital function in one plant but not in another. The selectivity of pesticides is not particularly unique. For example, mouthwash is employed in an attempt to kill certain organisms (bacteria) without killing another organism (the user). But with herbicides, the differences between target species and desirable species are often quite limited. Nevertheless, there are numerous reasons why weeds can sometimes be controlled selectively in a desired crop.

Contacting the Plant. Selectivity is often achieved mechanically through the use of directed sprays, or shields that restrict the spray to the weeds while protecting the crop. A common mechanism of selectivity involves a differential rooting depth between the weed and crops; selectivity in this case depends on the use of herbicides of sufficiently low water-solubility and/or strong soil-adsorption characteristics such that they do not penetrate deeply, and are thus able to control shallow-rooted weeds without harming deeper-rooted crops, particularly perennials. The use of simazine in orchards is one example.

Selectivity might also be achieved by timing the spray application. The application of paraquat to control emerged weeds immediately prior to emergence of the crop plant can be considered an example of such selectivity.

Penetration into the Plant. If the crop plant has waxy leaves and an upright growth form, her-

Figure 17. Interaction of many soil factors that determine the fate of herbicides; from [22]

bicides that are prone to run off might be used to control weeds lacking those characteristics. For example, dinoseb can be used to control mustards and other easily-wet weeds selectively in peas because the spray does not penetrate into the pea leaves. Onions can withstand some herbicides such as bromoxynil because of their upright, waxy leaves.

Differences in Grass-Seedling Morphology. The morphology of various grass seedlings differs as they emerge. With some species (Type I), the mesocotyl elongates, pushing the base of the coleoptile upward to a point near the soil surface. Most grasses tend to germinate in this way. On the other hand, in certain grasses (Type III) the mesocotyl does not elongate, and the base of the coleoptile remains at the seed. The coleoptile extends from the seed to the soil surface. Only later does an internode elongate, bringing the inflorescence primordia and leaf primordia near the soil surface, but this time *within* the coleoptile. Some herbicides are highly active when the region around the base of the coleoptile is exposed, because this region is rich in metabolic activity. It is here that the inflorescence primordia, leaf primordia, and future nodes are located. In Type III grasses this region approaches the soil surface very late, and it is somewhat protected by being within the coleoptile sheath. Type II grasses (oats, maize) are intermediate between Type I and Type III. Type I grasses include a great many species, whereas Type III consists largely of wheat, barley, rye, goatgrass, and a very few others. Consequently, selectivity might be achieved as a result of a difference in seedling morphology. For example, wheat seeded directly in trifluralin-treated soil will almost certainly be killed. However, trifluralin is registered (see Section 7.11) for the selective control of Type I grasses in wheat. This selectivity can be achieved only by planting the wheat seed more deeply than the trifluralin-treated soil. The base of the coleoptile of the Type I grasses (*Setaria, Echinochloa, Digitaria*) passes into the trifluralin-treated soil, whereas the base of the coleoptile in wheat remains at the seed and escapes injury.

Rapid Metabolism. Much more rapid degradation of a herbicide by the crop plant than by a weed is a common mechanism for biochemical selectivity. There are numerous examples of this type of selectivity, including atrazine in maize, terbacil in mint, diclofop in wheat, etc. In some cases the herbicide may not be rapidly destroyed, but rather conjugated with some cell component. Biochemical selectivity is generally more favorable, because it is less affected by environmental conditions than are mechanisms such as differential rooting depth.

Lack of Activation. A special type of biochemical selectivity is illustrated by the phen-

oxybutyric acids 2,4-DB and MCPB. Those two compounds are inactive as applied, and must be broken down within the plant through β-oxidation to 2,4-D and MCPA, respectively. Fortunately, most legume seedlings are unable to accomplish that conversion, and are spared herbicidal damage. Most broadleaf weeds can carry out β-oxidation readily, in effect committing chemical suicide.

Differences in Enzyme Form. In investigating the mechanism of resistance in populations that had become highly resistant to the *s*-triazine herbicides, it was discovered that the attachment protein within the chloroplast, where these materials exert their effect, had undergone a change. The herbicides could no longer attach to their site of action, and were therefore rendered ineffective. The fatty acid synthesis inhibitors (fluazifop, diclofop, sethoxydim, quizalofop) are highly selective in broadleaf crops because the corresponding acetyl CoA carboxylase enzyme displays differences such that the herbicides cannot attach to it, and is thus rendered ineffective. Unfortunately, normally sensitive species may include in their populations an appreciable number of individual plants with an altered form of enzyme, with the result that after only a few applications of an ACC-ase inhibitor, a herbicide-resistant population may be selected out.

7.7. Examples of Important Herbicides and Herbicide Groups

Thousands of formulations of 150 – 200 herbicides are used commercially around the world. Coverage here is limited to a brief introduction to selected groups and to properties of selected herbicides given in Section 7.8. Fortunately, excellent herbicide manuals containing more detailed information are available in many countries, including the United States [10], the United Kingdom [6], Germany [4], and France [3].

7.7.1. Foliage-Active Contact Herbicides

This group includes herbicides whose action occurs primarily through the foliage, and whose movement within the plant is very restricted. Damage from these herbicides is limited primarily to those tissues with which they make contact, so good spray coverage is especially important.

The *bipyridiliums* include paraquat, diquat, and a few others that are less widely used. Paraquat and diquat can injure or kill both grasses and broadleaves. They are rapidly absorbed into leaf tissue, and thus are not readily washed off by rainfall. They kill plants by accepting an electron in the photosynthetic process, leading to a proliferation of strong oxidizing agents that rapidly destroy plant membranes and other cell components. Consequently, bypyridiliums exert their toxic effects more rapidly in bright sunlight than in subdued light. Because they exist in the form of divalent cations, they are rapidly and tightly bound to soil particles, thus providing no soil activity in mineral soils. Bipyridiliums are used for controlling weeds prior to the planting of a crop, as directed sprays in ornamentals and orchards, in aquatics, as desiccants, as dormant applications to perennial crops, and in other applications. They are among the herbicides most toxic to mammals.

The *benzonitriles* include bromoxynil and ioxynil, which are primarily foliage-active nontranslocated herbicides. Dichlobenil is also a benzonitrile, but its mode of action is different. Bromoxynil and ioxynil are used primarily to control small broadleaves in grains and other grass crops, but may also be used in crops such as legumes. These materials inhibit respiration and perhaps photosynthesis as well.

Propanil is widely used for controlling weeds, primarily grasses, in rice. It is rapidly degraded in plants and soil, and inhibits photosynthesis.

Bentazon selectively controls certain broadleaf and sedge weeds in most grass crops and many large-seeded legume crops. Its activity in soil is relatively low, and its persistence is generally limited to six weeks or less. It inhibits photosynthesis.

Dinoseb is used in some countries (but not in the United States, where it is unavailable) both in the form of the parent phenol and as salts. The parent phenol is relatively nonselective, and is used as a general desiccant, in directed sprays for perennial crops, and for broad-spectrum knockdown on canal banks, etc. The salts are much more selective, and may be used

to control broadleaf weeds in many crops, including small grains, legumes, and flax. It is general biocide, and can inhibit growth of pathogens and such soil fauna as earthworms. It also is relatively toxic to mammals. Dinoseb inhibits respiration in both plants and animals.

Various phytotoxic oils can also be used directly for weed control. Unlike the nonphytotoxic oils used as adjuvants, phytotoxic oils are more highly unsaturated, and they tend to have a high content of aromatics. They are also sometimes used in conjunction with herbicides to improve uptake into brushy species.

7.7.2. Foliage-Active Translocated Herbicides

The *growth regulators*, or auxin-type herbicides, have been widely used around the world for several decades (→ Chlorophenoxyalkanoic Acids). This group includes 2,4-D, MCPA, 2,4,5-T, picloram, dicamba, clopyralid, triclopyr, and others. Their selectivities differ, but the mechanism of herbicidal action, which is not completely understood, seems to be uniform. Auxin-type herbicides primarily succeed in controlling broadleaf weeds selectively in grass crops. Their discovery in the early 1940s was largely responsible for a tremendous increase in interest in herbicides, and it is widely regarded as a turning-point in weed-control history. These materials are translocated in the phloem in a source-to-sink manner. For this reason, timing and moisture status of the plant are critical in controlling deep-rooted perennial broadleaves. Soil persistence ranges from as little as 2–4 weeks in the case of 2,4-D to perhaps several months for picloram. Their acute mammalian toxicity varies widely, from 300–1000 mg/kg in rats for the phenoxy group, less toxicity with dicamba, to very low toxicities with clopyralid and picloram. The exact mechanism of physiological action remains elusive, but evidence indicates an association with a rapid effect on the proton pump in the cell membrane, and a slower effect on RNA synthesis, perhaps leading to abnormal enzyme synthesis.

The *fatty acid synthesis inhibitors* include diclofop, fluazifop-P, sethoxydim, quizalofop, tralkoxydim, and clethodim. These materials control a wide spectrum of grasses, but display very low toxicity with respect to broadleaf species. Unfortunately, this group tends to develop resistant populations quite rapidly. Most of the members are translocated both in the xylem and the phloem. Compounds in this category block fatty acid synthesis by inhibiting acetyl CoA carboxylase. Broadleaves as well as fine fescues (*Vulpia* sp.) are tolerant, because they have a different form of this enzyme than most grasses.

Glyphosate is widely used throughout the world. It is a nonselective, general weed killer, controlling annual and perennial broadleaves as well as grasses. It is used in both cropland and noncropland situations. Selectivity can be achieved by differential timing or placement of herbicide application in relation to crop growth. Because glyphosate has little or no soil activity, registered crops can be planted immediately after application. It is absorbed through the foliage, and moves throughout the plant in the symplast in a source-to-sink manner. It kills plants by inhibiting an enzyme in the synthetic pathway for aromatic amino acids (→ Plant Growth Regulators). Because this pathway is not present in mammals, glyphosphate's toxicity to mammals is very low.

The *sulfonylureas* (SU) include chlorsulfuron, metsulfuron, sulfometuron, rimsulfuron, chlorimuron, primisulfuron, triasulfuron, and several others. The *imidazolinones* include imazamethabenz, imazapyr, imazaquin, imazethapyr, and others. Characteristics of individual herbicides within these groups vary widely, as do selectivity and uses. Soil persistence ranges from very brief to greater than a year. The sulfonylurea group in particular illustrates the variation in selectivity that can be achieved by changes in molecular structure. Some of the SUs are extremely toxic to sugar beets, for example, whereas other related compounds can be used selectively with sugar beets. Both groups inhibit plant growth by blocking an enzyme in the biochemical pathway for synthesis of the branched-chain amino acids valine, leucine, and isoleucine. This pathway is unique to plants, so these compounds display very low toxicity in mammals.

Other foliage-active, translocated herbicides include amitrole and the organic arsenicals.

7.7.3. Soil-Active Herbicides

Photosynthesis inhibitors include the phenylureas (diuron, chlorbromuron, isoproturon, etc.), the *s*-triazines (atrazine, simazine, cyanazine), uracils (bromacil, terbacil), and pyrazon. These materials are commonly called Hill-reaction inhibitors because they block electron transport in photosystem II. The compounds are absorbed by roots and transported upward in the xylem, after which they move into greenleaf tissue where they exert their toxic effects. Commonly, selectivity is a consequence of differences in rooting depth between the crop and the weed, but there are notable examples of differential metabolic rates, as with the *s*-triazines in corn and terbacil in mint. None are highly volatile nor readily photodecomposed. Soil persistence varies, but frequently can reach one or more years, depending on climatic conditions and initial application rate. Because the compounds operate primarily on a system unique to plants, toxicity to mammals is considered very low. Plant death does not result from starvation alone. Chlorophyll 680 continues to absorb solar energy even when electron transport is blocked, but it is unable to dissipate the energy. This results in highly oxidized cell products, leading to membrane destruction. Therefore, phytotoxicity is a result of both electron-transport blockage and the absorption of light, explaining why the products work more rapidly in bright sunlight than in dim light. The first *s*-triazines introduced, simazine and atrazine, have been used extensively in maize, but use of these two herbicides, as well as others in the group, has expanded to selective applications in perennial crops, orchards, and noncrop situations.

The *dinitroanilines* or *dinitrobenzeneamines* include trifluralin, benefin, oryzalin, pendimethalin, and ethalfluralin, among others. The strength of these materials is in controlling annual grasses, but they can also control certain broadleaf weeds. Most are so volatile that they must be incorporated into the soil to prevent vapor loss. Although these substances are effective at inhibiting root growth, the primary mechanism of plant death requires uptake into the emerging grass shoots. None of the materials are effective when applied postemergence to existing weeds, but they are commonly applied before a crop is planted for incorporation into the soil, or applied following crop planting and incorporated above the crop seed. Uses for members of this group can include weed control in soybeans, cotton, small-seeded legumes, beans, cole crops, umbelliferous crops, potatoes, sugarcane, and many others. The herbicides are orange – yellow in color, and they kill plants by preventing the polymerization of tubulin to form microtubules. Their toxicity to mammals is quite low.

The *diphenyl ether* herbicides include acifluorfen, nitrofen, and oxyfluorfen. They mostly control annual broadleaf weeds, but can provide control over some grass species as well. One or more members of the group can be used for weed control in a wide variety of crops, including soybeans, cole crops, umbelliferous crops, and mint. Toxicity to mammals is considered moderate to low. These materials kill plants by inhibiting protoporphyrinogen oxidase, which probably causes unprocessed protoporphyrinogen to diffuse out of its normal localized site in the chloroplast to become oxidized by molecular oxygen in an unregulated manner. This results in a large accumulation of protoporphyrin IX, leading to excessive absorption of light and subsequent oxidation of membranes. Light is required for the phytotoxic action of this group.

The *thiocarbamate* or *carbamothioate* group includes EPTC, butylate, cycloate, triallate, and vernolate. This group is used primarily for controlling annual and perennial grasses in broadleaf crops and in maize. EPTC was the first representative of this group, and it is used in a wide variety of crops, including small- and large-seeded legumes, maize, potatoes, flax, sunflower, and many others. Cycloate is used primarily for weed control in sugar beets and spinach, whereas triallate is widely used for control of wild oats in small grains and in peas and lentils. These materials are volatile, and must be incorporated into the soil surface fairly soon after application. They are low in toxicity to mammals, and they kill plants by entry into the shoots of emerging grasses. The exact mechanism of herbicidal action is not known, although considerable evidence points toward an involvement with lipid metabolism.

The *substituted amides* include alachlor, metolachlor, butachlor, propachlor, napropamide, and pronamide. Characteristics of the several members of this group vary

widely. The substituted acetanilides (alachlor, butachlor, metolachlor) are most effective on annual grasses as a result of surface application following planting of the crop. Alachlor and metolachlor are used extensively in maize and soybean, whereas butachlor is primarily used in rice. Their activity requires uptake into the shoots of emerging grasses. Napropamide is one of the few herbicides in which photodecomposition is so significant that it must be incorporated into the soil within a day or two during sunny weather. Toxicity to mammals is moderate for a few of the herbicides, but very low with most of the members of this group.

7.8. Properties of Herbicides

7.8.1. Diphenyl Ethers

Acifluorfen [*50594-66-6*], 5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrobenzoic acid, $C_{14}H_7ClF_3NO_5$, M_r 361.7, *mp* 142 – 160 °C, is a light brown solid which is sparingly soluble in water and soluble in acetone, ethanol, dichloromethane, xylene, and kerosene [23, p. 12].

Acifluorfen is produced by reaction of 2-chloro-4-trifluoromethylphenol with 2-nitro-5-chlorobenzoic acid [25].

Acifluorfen is a selective contact herbicide which is absorbed by foliage and roots, with negligible translocation. It is used post-emergence for the control of annual broad-leaved weeds, with some effects on grasses.

Trade Names. Blazer, Doble, Galaxy, Storm (BASF).

Aclonifen [*74070-46-5*], 2-chloro-6-nitro-3-phenoxyaniline, $C_{12}H_9ClN_2O_3$, M_r 264.7, *mp* 81 – 82 °C, consists of yellow crystals which are practically insoluble in water but soluble in methanol, hexane, and toluene [23, p. 14].

Aclonifen is manufactured by reaction of 1,2-dichloro-3-amino-4-nitrobenzene with phenolate [26].

Aclonifen is a selective, systemic herbicide used pre-emergence to control grass and broad-leaved weeds in winter wheat, potatoes, sunflowers, and other crops.

Trade Name. Challenge (Rhône-Poulenc).

AKH-7088 [*104459-82-7*], methyl (*E,Z*)-1-[5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrophenyl]-2-methoxyethylidene amino-oxyacetate, $C_{19}H_{16}ClF_3N_2O_7$, M_r 476.8, *mp* 57.7 – 58.1, forms colorless crystals which are sparingly soluble in water [23, p. 22].

AKH-7088 is produced by reaction of 2-chloro-*p*-trifluoromethylphenolate with 3-methoxyethylidineamino-oxyacatate 4-nitrochlorobenzene [27].

AKH-7088 is used post-emergence to control broad-leaved weeds, and velvet leaf in soya beans.

Trade Name. To be announced (Asahi).

Bifenox [*42576-02-3*], methyl 5-(2,4-dichlorophenoxy)-2-nitrobenzoate, $C_{14}H_9Cl_2NO_5$, M_r 342.1, *mp* 84 – 86 °C, consists of yellow crystals which are practically insoluble in water, readily soluble in acetone, chlorobenzene, xylene, and ethanol, and slightly soluble in aliphatic hydrocarbons [23, p. 116].

Bifenox is produced by reaction of potassium 2,4-dichlorophenolate with methyl 5-chloro-2-nitrobenzoate [28].

Bifenox acts by cellular membrane disruption and by inhibition of photosynthesis. It is a selective herbicide used to control broad-leaved weeds and some grasses in cereals, maize, and soya beans.
Trade Names. Modown, Tolkan (Rhône-Poulenc).

Chlomethoxyfen [*32861-85-1*], 5-(2,4-dichlorophenoxy)-2-nitroanisole, $C_{13}H_9Cl_2NO_4$, M_r 314.1, *mp* 113 – 114 °C, consists of yellow crystals which are practically insoluble in water, and are readily soluble in acetone, dimethyl sulfoxide, and benzene [23, p. 200].

Chlomethoxyfen is obtained by reaction of 2,4-dichlorophenolate with 1-chloro-3-methoxy-4-nitrobenzene [29].

Chlomethoxyfen is a selective contact herbicide used pre-emergence for the control of annual weeds in transplanted rice.
Trade Names. Diphenex (Ishihara Sangyo); Ekkusugoni (Nihon Nohyaku, Ishihara Sangyo).

Fluoroglycofen-ethyl [*77501-90-7*], *O*-[5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrobenzoyl]glycolic acid, $C_{18}H_{13}ClF_3NO_7$, M_r 447.8, *mp* 65 °C, forms a dark amber solid which is practically insoluble in water and is readily soluble in most organic solvents [23, p. 580].

Fluoroglycofen-ethyl is produced by reaction of 5-[2-chloro-4-(trifluoromethyl)phenyl]-2-nitrobenzoyl chloride with ethyl hydroxyacetate in the presence of trimethylamine [30].

Fluoroglycofen-ethyl is a selective leaf and root herbicide used to control broad-leaved weeds and grasses in wheat, barley, oats, peanuts, rice, and soya beans.
Trade Names. Compete (Rohm & Haas); Satis (Novartis).

Fomesafen [*72178-02-0*], 5-(2-dichloro-α,α,α-trifluoro-*p*-tolyloxy)-*N*-methylsulfonyl-2-nitrobenzamide, $C_{15}H_{10}ClF_3N_2O_6S$, M_r 438.8, *mp* 220 – 221 °C, forms colorless crystals which are moderately soluble in water [23, p. 616].

Fomesafen is manufactured by reaction of 2-chloro-4-trifluoromethylphenolate with 4-chloro-*N*-methylsulfonyl-2-nitrobenzamide [31].

Fomesafen is a selective herbicide which is absorbed by both leaves and roots. It is used in early post-emergence for the control of broad-leaved weeds in soya beans.
Trade Names. Flex, Reflex (Zeneca).

HC-252 [*131086-42-5*], ethyl *O*-[2-chloro-5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy) benzoyl]-L-lactate, $C_{19}H_{15}Cl_2F_3O_5$, M_r 451.0, is a brown oily viscous liquid which is readily soluble in acetone, methanol, and xylene [23, p. 663].

HC-252 is produced by reaction of 2-chloro-5-[2-chloro-4-(trifluoromethyl)phenoxy]benzoyl chloride with ethyl acetate [32].

HC-252 acts by accumulation of tetrapyrrole and protoporphyrin. It is a contact herbicide for the control of broad-leaved weeds in winter wheat, barley, peas, soya beans, and peanuts.
*Trade Name.*To be announced (Budapesti Vegyimüvek).

Lactofen [*77501-63-4*], ethyl *O*-[5-(2-chloro-α,α,α-trifluoro-*p*-tolyloxy)-2-nitrobenzoyl]-DL-lactate, $C_{19}H_{15}ClF_3NO_7$, M_r 461.8, is a dark brown to tan solid which is sparingly soluble in water [23, p. 747].

Lactofen is produced by reaction of 2-chloro-4-trifluoromethylphenolate with ethyl 2-nitro-5-chlorobenzoyllactate [33].

Lactofen is applied to control broad-leaved weeds in cereals, potatoes, soya beans, rice, and peanuts.

Trade Name. Cobra (Valent, PPG, Sumitimo).

Oxyfluorfen [*42874-03-3*], 2-chloro-α,α,α-trifluoro-*p*-tolyl 3-ethoxy-4-nitrophenyl ether, $C_{15}H_{11}ClF_3NO_4$, M_r 361.7, *mp* 85 – 90 °C, is an orange crystalline solid which is practically insoluble in water and readily soluble in most organic solvents [23, p. 919].

Oxyfluorfen is manufactured by reaction of 3,4-dichlorobenzotrifluoride with resorcinol; the resulting product is then treated with ethanol in the presence of potassium hydroxide [34].

Oxyfluorfen is a selective contact herbicide used pre- and post-emergence for the control of annual broad-leaved weeds in a variety of tropical and subtropical crops.

Trade Names. Goal (Rohm & Haas); Galigan (Markhteshim-Agan), etc.

7.8.2. Sulfonylureas

Amidosulfuron [*120923-37-7*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-mesyl(methyl)sulfamoylurea, $C_9H_{15}N_5O_7S_2$, M_r 369.4, *mp* 160 – 163 °C, is a colorless crystalline powder which is sparingly soluble in water and moderately soluble in isopropyl alcohol, methanol, and acetone [23, p. 37].

Amidosulfuron is produced by reaction of *N*-methylmesylsulfonamide with chlorosulfonyl isocyanate, followed by treatment with 2-amino-4,6-dimethoxypyrimidine [35].

Amidosulfuron is a selective, systemic herbicide used post-emergence for the control of a wide range of broad-leaved weeds, especially cleavers, in winter wheat, durum wheat, barley, rye, and oats.

Trade Name. (AgrEvo).

Azimsulfuron [*120162-55-2*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-[1-methyl-4-(2-methyl-2*H*-tetrazol-5-yl)pyrazol-5-ylsulfonyl]urea, $C_{13}H_{16}N_{10}O_5S$, M_r 424.4, *mp* 170 °C, is a colorless solid which is moderately soluble in water, acetone, acetonitrile, ethyl acetate, and methanol [23, p. 63].

Azimsulfuron is produced by reaction of 2-(1-methyl-1*H*-diazol)-4-(1-methyl-1*H*-tetrazol)-sulfonamide with 2-(4,6-dimethoxypyrimidine)isocyanate [37].

Azimsulfuron is a post-emergence herbicide with mainly foliar uptake. It is used to control annual and perennial broad-leaved and sedge weeds in southern European rice.

Trade Name. Gulliver (Du Pont).

Bensulfuron-methyl [*83055-99-6*], methyl α-(4,6-dimethoxypyrimidin-2-ylcarbamoylsulfamyl)-*o*-toluate, $C_{16}H_{18}N_4O_7S$, M_r 410.4, *mp* 185 – 188 °C, is a colorless to pale yellow solid which is sparingly soluble in water and is fairly soluble in acetone, acetonitrile, chloromethane, and ethyl acetate [23, p. 104].

Bensulfuron-methyl is produced by the reaction between 2-carboxymethyl benzylsulfamaoyl chloride and 2-amino-4,6-dimethoxypyrimidine [37].

Bensulfuron-methyl is a selective, systemic herbicide used pre- and post-emergence for the control of annual and perennial weeds and sedges in continuously flooded rice.

Trade Names. Fujigrass (Du Pont, Zeneca), Londax, Zark (Du Pont); Wolf-Ace (Kumiai), etc.

Chlorimuron-ethyl [*90982-32-4*], ethyl 2-(4-chloro-6-methoxypyrimidin-2-ylcarbamoylsulfamoyl)benzoate, $C_{15}H_{15}ClN_4O_6S$, M_r 414.8, *mp* 181 °C, consists of colorless crystals which are moderately soluble in water and slightly soluble in organic solvents [23, p. 217].

Chlorimuron-ethyl is produced by reaction of ethyl 2-sulfamoylchloride benzoic acid with 2-amino-4-chloro-6-methoxypyrimidin [38].

Chlorimuron-ethyl is used post-emergence for the control of broad-leaved weeds in soya beans and peanuts.

Trade Names. Classic (Du Pont); Darban (IPESA), etc.

Chlorsulfuron [*64902-72-3*], 1-(2-chlorophenylsulfonyl)-3-methyl-1,3,5-triazin-2-yl)urea, $C_{12}H_{12}N_5O_4S$, M_r 357.8, *mp* 170 – 173 °C, forms a colorless crystalline solid which is sparingly soluble in water and readily soluble in dichloromethane, acetone, methanol, toluene, and hexane [23, p. 239].

Chlorsulfuron is produced by reaction of 2-sulfonylisocyanate chlorobenzene with 2-amino-4,6-dimethoxy-1,3,5-triazine [39].

Chlorsulfuron is a selective, systemic herbicide used pre- and early post-emergence for the control of most broad-leaved weeds and some grasses in wheat, barley, oats, rye, and noncropland.

Trade Names. Glean, Telar (Du Pont); Lasher (Sanonda), etc.

Cinosulfuron [*94593-91-6*], 1-(4,6-dimethoxy-1,3,5-triazin-2-yl)-3-[2-(2-methoxyethoxy)phenylsulfonyl]urea, $C_{15}H_{19}N_5O_7S$, M_r 413.4, *mp* 127.0 – 135.2 °C, is a colorless crystalline powder which is fairly soluble in water and is readily soluble in acetone, ethanol, toluene, and *n*-octanol [23, p. 148].

Cinosulfuron is produced by reaction of 2-methoxyethoxy sulfamoyl chlorobenzene with 2-amino-4,6-dimethoxy-1,3,5-triazine [40].

Cinosulfuron is used post-emergence to control many weeds in transplanted, directly seeded, wet-sown, water-sown, and dry-sown flooded rice crops. It is also used in tropical plantation crops.

Trade Name. Setoff (Novartis).

Ethametsulfuron-methyl [*97780-06-8*], methyl 2-[(4-ethoxy-6-methylamino-1,3,5-triazin-2-yl)carbamoylsulfamoyl]benzoate, $C_{15}H_{18}N_6O_6S$, M_r 410.4, *mp* 194 °C, consists of colorless to light tan crystals which are sparingly soluble in water and are moderately soluble in acetone, acetonitrile, ethanol, methanol, and dichloromethane [23, p. 475].

Ethametsulfuron-methyl is produced by reaction of methyl 2-sulfamoylbenzoate with 4-

ethoxy-6-methylamino-1,3,5-triazin-2-yl isocyanate [41].

Ethametsulfuron-methyl is used post-emergence to control wild mustard, hempnettle, and other broad-leaved weeds in oilseed rape.
Trade Name. Muster (Du Pont).

Ethoxysulfuron [*126801-58-9*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-(2-ethoxyphenoxysulfonyl)urea, $C_{15}H_{18}N_4O_7S$, M_r 398.4, *mp* 144 – 147 °C, is a colorless to beige powder which is moderately soluble in water [23, p. 488].

Ethoxysulfuron is produced by reaction of 2-ethoxyphenoxysulfonyl isocyanate with 2-amino-4,6-dimethoxypyrimidine [42].

Ethoxysulfuron is under development for the control of broad-leaved and sedge weeds in cereals, rice, and sugar cane.
*Trade Name.*To be announced (AgrEvo).

Flazasulfuron [*104040-78-0*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-(3-trifluoromethyl-2-pyridylsulfonyl)urea, $C_{13}H_{12}F_3N_5O_5S$, M_r 407.3, *mp* 166 – 170 °C, consists of colorless crystals which are readily soluble in water, methanol, acetone, and toluene [23, p. 550].

Flazasulfuron is produced by reaction of 2-sulfamoylchloride-3-trifluoromethylpyridine with 2-amino-4,6-dimethoxypyrimidine [43].

Flazasulfuron is used post-emergence for the control of grass and broad-leaved weeds and sedges in warm-season turf.
Trade Names. Katana, Shibagen (Ishihra Sangyo).

Flupyrsulfuron-methyl-sodium [*144740-54-5*], methyl 2-(4,6-dimethoxypyrimidin-2-ylcarbamoylsulfamoyl)-6-trifluoromethylnicotinate monosodium salt, $C_{15}H_{13}F_3N_5NaO_7S$, M_r 487.3, *mp* 165 – 170 °C, is a colorless powder which is sparingly soluble in water, and moderately soluble in dichloromethane, acetone, ethyl acetate, and acetonitrile [23, p. 586].

Flupyrsulfuron-methyl-sodium is produced by reaction of methyl 2-aminosulfonyl-6-trifluoromethyl-3-pyridine carboxylate with 4,6-dimethoxypyrimidin-2-yl isocyanate [44].

Flupyrsulfuron-methyl-sodium is under development for selective post-emergence control of black grass and other weeds in cereals.
*Trade Name.*To be announced (Du Pont).

Halosulfuron-methyl [*100784-20-1*], methyl 3-chloro-5-(4,6-dimethoxypyrimidin-2-ylcarbamoylsulfamoyl)-1-methylpyrazole-4-carboxylate, $C_{13}H_{15}ClN_6O_7S$, M_r 434.8, *mp* 175.5 – 177.2 °C, is a colorless powder which is moderately soluble in water and methanol [23, p. 657].

Halosulfuron-methyl is produced by reaction of *N*-1-methyl-3-chloro-4-carboxymethyl-5-sulfonylisocyanate pyrazole with 2-amino-4,6-dimethoxypyrimidine [45].

Halosulfuron-methyl is used to control annual broad-leaved weeds and nutsedge sp. in maize, sugar cane, and turf.
Trade Name. (Nissan, Monsanto).

Imazosulfuron [*122548-33-8*], 1-(2-chloroimidazo[1,2-*a*]pyridin-3-ylsulfonyl)-3-(4,6-dimethoxypyrimidin-2-yl)urea, $C_{14}H_{13}ClN_6O_5S$, M_r 412.8, *mp* 183 – 184 °C, is a crystalline powder which is sparingly soluble in water and is fairly soluble in acetonitrile,

acetone, xylene, dichloromethane, and ethyl acetate [23, p. 703].

Imazosulfuron is produced by reaction of 2-chloroimidazo[1,2-*a*]pyridine sulfonylisocyanate with 2-amino-4,6-dimethoxypyrimidine [46].

Imazosulfuron is used to control most annual and perennial broad-leaved weeds and sedges in paddy rice and turf.

Trade Names. Sibatito, (Takeda).

Metsulfuron-methyl [*74223-64-6*], methyl 2-(4-methoxy-6-methyl-1,3,5-triazin-2-ylcarbamoylsulfamoyl)benzoate, $C_{14}H_{15}N_5O_6S$, M_r 381. 4, *mp* 158 °C, consists of colorless crystals which are fairly soluble in water, xylene, ethanol, methanol, and acetone [23, p. 842].

Metsulfuron-methyl is produced by reaction of 2-sulfamoylchloride benzoic acid with 2-amino-4-methoxy-6-methyl-1,3,5-triazine [47].

Metsulfuron-methyl is a selective systemic herbicide used to control a wide range of annual and perennial broad-leaved weeds in wheat, barley, rice, and oats, by pre- or post-emergence application.

Trade Names. Ally (Du Pont); Malban (IPESA); Quit (Sanonda), etc.

Nicosulfuron [*111991-09-4*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-(3-dimethylcarbamoyl-2-pyridinylsulfonyl)urea, $C_{15}H_{18}N_6O_6S$, M_r 410.4, *mp* 141 – 144 °C, consists of colorless crystal which are moderately soluble in water and are readily soluble in acetone, ethanol, chloroform, dimethylformamide, acetonitrile, and dichloromethane [23, p. 877].

Nicosulfuron is produced by reaction of 2-sulfamoylchloride-3-*N*-dimethylamino-carboxypyridine with 2-amino-4,6-dimethylpyrimidine [48].

Nicosulfuron is a selective, systemic herbicide used post-emergence to control annual grass weeds in maize.

Trade Names. Accent (Du Pont); Dasul (Ishihara Sangyo, Dr. Maag); Nostoc (IPESA); Milagro (Ishihara Sangyo, Zeneca), etc.

Oxasulfuron [*144651-06-9*], oxetan-3-yl 2-[(4,6-dimethylpyrimidin-2-yl)-carbamoylsulfamoyl]benzoate, $C_{17}H_{18}N_4O_6S$, M_r 406.4, *mp* 158 °C (decomp.), is a colorless powder which is moderately soluble in water and fairly soluble in methanol, acetone, toluene, and dichloromethane [23, p. 911].

Oxasulfuron is produced by reaction of 2-[[(3-oxetanyl)oxy]carbonyl]benzenesulfonamide with 4,6-dimethylpyrimidine-2-yl carbamate [49].

Oxasulfuron is under development for the control of broad-leaved and grass weeds in soya beans.

Trade Names. Expert, Dynam (Novartis).

Primisulfuron-methyl [*86209-51-0*], methyl 2-[4,6-bis(difluoromethoxy)pyrimidin-2-ylcarbamoylsulfamoyl]benzoate, $C_{15}H_{12}F_4N_4O_7S$, M_r 468.3, *mp* 194.8 – 197.4 °C, is a fine colorless powder which is sparingly soluble in water and readily soluble in acetone, ethanol, and toluene [23, p. 997].

Primisulfuron-methyl is produced by reaction of 2-sulfamoylchloride benzoic acid with 2-amino-4,6-difluoromethoxypyrimidine [50].

Primisulfuron-methyl is a selective, systemic herbicide used post-emergence for the control of problem weeds and many broad-leaved weeds in maize.

Trade Names. Beacon, Tell (Novartis).

Prosulfuron [*94125-34-5*], 1-(4-methoxy-6-methyl-1,3,5-triazin-2-yl)-3-[2-(3,3,3-trifluoropropyl)phenylsulfonyl]urea, $C_{15}H_{16}F_3N_5O_4S$, M_r 419.4, *mp* 155 °C (decomp.), consists of colorless crystals which are sparingly soluble in water and readily soluble in ethanol, acetone, toluene, ethyl acetate, and dichloromethane [23, p. 1041].

Prosulfuron is produced by reaction of 2-(3,3,3-trifluoropropyl)phenylsulfamoylchloride with 2-amino-4-methyl-6-methoxypyrimidine [51].

Prosulfuron is used post-emergence on maize, sorghum, cereals, pasture, and turf for broad-spectrum control of annual broad-leaved weeds.

Trade Names. Exceed, Peak (Novartis).

Pyrazosulfuron-ethyl [*93697-74-6*], ethyl 5-(4,6-dimethoxypyrimidin-2-ylcarbamoylsulfamoyl)-1-methylpyrazole-4-carboxylate, $C_{14}H_{18}N_6O_7S$, M_r 414.4, *mp* 181 – 182 °C, consists of colorless crystals which are sparingly soluble in water and fairly soluble in benzene, chloroform, and acetone [23, p. 1052].

Pyrazosulfuron-ethyl is produced by reaction of *N*-1-methyl-4-carboxy-5-sulfonylisocyanate pyrazole with 2-amino-4,6-dimethoxypyrimidine [52].

Pyrazosulfuron-ethyl is a systemic herbicide used pre- and post-emergence to control annual and perennial broad-leaved weeds and sedges in wet-sown and transplanted rice crops.

Trade Names. Sparkstar (Novartis, Nisson, Zeneca); Sirius, (Nissan); Act (Nihon Bayer, Nissan); Billy (Sanonda), etc.

Rimsulfuron [*122931-48-0*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-(3-ethylsulfonyl-2-pyridylsolfonyl)urea, $C_{14}H_{17}N_5O_7S_2$, M_r 431.4, *mp* 176 – 178 °C, consists of colorless crystals which are fairly soluble in buffered solution (pH 7) [23, p. 1095].

Rimsulfuron is produced by reaction of 2-sulfamoylchloride-3-sulfonylethylpyridine with 2-amino-4,6-dimethoxypyrimidine [53].

Rimsulfuron is used post-emergence to control annual and perennial grasses and several broad-leaved weeds in maize.

Trade Name. (Du Pont).

Sulfometuron-methyl [*74222-97-2*], methyl 2-(4,6-dimethylpyrimidin-2-ylcarbamoylsulfamoyl)benzoate, $C_{15}H_{16}N_4O_5S$, M_r 363.4, *mp* 203 – 205 °C, is a colorless solid which is sparingly soluble in water and fairly soluble in acetone, acetonitrile, dichloromethane, and dimethyl sulfoxide [23, p. 1128].

Sulfometuron-methyl is produced by reaction of 2-sulfonylisocyanate methylbenzoate with 2-amino-4,6-dimethylpyrimidine [54].

Sulfometuron-methyl is used to control annual and perennial grasses and broad-leaved weeds in noncropland, as well as in forestry to control woody tree species in pine forests.
Trade Name. Oust (Du Pont).

Sulfosulfuron [*141776-32-1*], 1-(4,6-dimethoxypyrimidin-2-yl)-3-(2-ethylsulfonylimidazo[1,2-*a*]pyridin-3-yl)sulfonylurea, $C_{16}H_{18}N_6O_7S_2$, M_r 470.8, *mp* 201.1 – 201.7 °C, is a colorless solid which is sparingly soluble in water [23, p. 1130].

Sulfosulfuron is produced by reaction of 2-ethylsulfonylimidazo[1,2-*a*]pyridine 3-sulfonamide with 4,6-dimethoxypyrimidin-2-yl isocyanate [55].

Sulfosulfuron is under development for the control of grasses and broad-leaved weeds in cereals.

To be announced (Monsanto, Takeda).

Thifensulfuron-methyl [*79277-27-3*], methyl 3-(4-methoxy-6-methyl-1,3,5-triazin-2-ylcarbamoylsulfamoyl)thiophen-2-carboxylate, $C_{12}H_{13}N_5O_6S_2$, M_r 387.4, *mp* 176 °C, consists of colorless crystals which are sparingly soluble in water and moderately soluble in methanol, ethyl acetate, acetone, and dichloromethane [23, p. 1188].

Thifensulfuron-methyl is produced by reaction of 2-(methoxycarbonyl)-3-thiophenesulfonyl isocyanate with 2-amino-4,6-dimethoxypyrimidine [56].

Thifensulfuron-methyl is used in winter and spring wheat, winter and spring barley, rye, triticale, oats, soya beans, etc.
Trade Names. Pinnacle, Harmony (Du Pont).

Triasulfuron [*82097-50-5*], 1-[2-(2-chloroethoxy)phenylsulfonyl]-3-(4-methoxy-6-methyl-1,3,5-triazin-2-yl)urea, $C_{14}H_{16}ClN_5O_5S$, M_r 401.8, *mp* 178.1 °C, is a fine colorless powder which is moderately soluble in water, ethanol, and *n*-hexane and is readily soluble in acetone, dichloromethane, and ethyl acetate [23, p. 1222].

Triasulfuron is produced by reaction of 2-chloroethoxyphenylsulfamoyl chloride with 2-amino-4-methoxy-6-methyl-1,3,5-triazine [57].

Triasulfuron is a selective herbicide used pre- and post-emergence for the control of broad-leaved weeds in wheat, barley, and triticale.
Trade Names. Logran, Satis (Novartis).

Tribenuron-methyl [*101200-48-0*], methyl 2-[4-methoxy-6-methyl-1,3,5-triazin-2-yl-*N*-methylcarbamoylsulfamoyl]benzoate, $C_{15}H_{17}N_5O_6S$, M_r 395.4, *mp* 141 °C, is a light brown solid which is moderately soluble in water (pH-dependent, increasing with pH) and is sparingly soluble in acetone, acetonitrile, carbon tetrachloride, ethyl acetate, hexane, and methanol [23, p. 1230].

Tribenuron-methyl is produced by reaction of methyl-2-sulfamoylchloride benzoic acid with 2-methylamino-4-methoxy-6-methyl-1,3,5-triazine [58].

Tribenuron-methyl is used post-emergence for the control of broad-leaved weeds in spring and winter cereals.
Trade Names. Express, Granstar, Pointer (Du Pont).

Triflusulfuron-methyl [*126535-15-7*], methyl 2-[4-dimethylamino-6-(2,2,2-trifluromethoxy)-1,3,5-triazin-2-ylcarbamoylsulfamoyl]-*m*-toluate, $C_{17}H_{19}F_3N_6O_6S_2$, M_r 492.4, *mp* 160 – 163 °C, is a colorless crystalline solid which is sparingly soluble in water (pH 7), dichloromethane, methanol, toluene, and acetonitrile [23, p. 1250].

Triflusulfuron-methyl is produced by reaction of methyl 2-sulfamoylchloride-3-methylbenzoate with 2-amino-4-dimethylamino-6-(2,2,2-trifluoroethoxy)-1,3,5-triazine [59].

Triflusulfuron-methyl is used post-emergence for the control of many annual and perennial broad-leaved weeds in sugar beet.
Trade Names. Debut, Safari, Upbeet (Du Pont).

7.8.3. Chloroacetanilides

Acetochlor [*34256-82-1*], 2-chloro-*N*-ethoxymethyl-6′-ethylaceto-*o*-toluidide, $C_{14}H_{20}ClNO_2$, M_r 269.8, *mp* < 0 °C, *bp* 162 °C/7 mmHg, is a wine red to yellow or amber oil which is sparingly soluble in water and readily soluble in diethyl ether, acetone, benzene, chloroform, ethanol, ethyl acetate, and toluene [23, p. 10].

Acetochlor is produced by reaction of chloroacetyl chloride with the azomethine of 2-ethyl-6-methylaniline and formaldehyde, followed by treatment with ethanol [60].

Acetochlor is a selective herbicide used pre-emergence or pre-planting to control annual grasses, certain annual broad-leaved weeds, and yellow nutsedge in maize, peanuts, soya beans, cotton, potatoes, and sugar cane.
Trade Names. Harness (Monsanto); Surpass, Trophy (Zeneca); Acenit (Nitrokemia), etc.

[*15972-60-8*], 2-chloro-2′,6′-diethyl-*N*-methoxymethylacetanilide, $C_{14}H_{20}ClNO_2$, M_r 269.8, *mp* 40.5 – 41.5 °C, is a yellow to wine red solid which is sparingly soluble in water and *n*-hexane and is readily soluble in diethyl ether, acetone, benzene, chloroform, ethanol, and ethyl acetate [23, p. 23].

Alachlor is synthesized by reaction of chloroacetyl chloride with the azomethine of 2,6-diethylaniline and formaldehyde, followed by treatment with methanol [60].

Alachlor is a selective, systemic herbicide used pre-emergence to control annual grasses and many broad-leaved weeds in cotton, brassicas, maize, oilseed rape, peanuts, etc.
Trade Names. Lasso (Monsanto); Alanex (Markhteshim-Agan); Lacorn (Efthymiadis); Satochlor (Sagrochem), etc.

Butachlor [*23184-66-9*], *N*-butoxymethyl-2-chloro-2′,6′-diethylacetanilide, $C_{17}H_{26}NO_2$, M_r 311.9, *mp* – 2.8 to 1.7 °C, *bp* 156 °C/0.5 mmHg, is a light yellow to purple liquid which is sparingly soluble in water and is readily soluble in most organic solvents [23, p. 159].

Butachlor is produced by reaction of chloroacetyl chloride with the azomethine of 2,6-diethylaniline and formaldehyde, followed by treatment with *n*-butanol [60].

Butachlor is a selective systemic herbicide used pre-emergence for the control of an-

nual grasses and certain broad-leaved weeds in seeded and transplanted rice.
Trade Names. Machete (Monsanto); Butataf (Ralis); Butanex (Makhteshim-Agan); Formachlor (Sanonda), etc.

Dimethachlor [*50563-36-5*], 2-chloro-*N*-(2-methoxyethyl)aceto-2′,6′-xylidide, $C_{13}H_{18}ClNO_2$, M_r 255.7, *mp* 45.8 – 46.7 °C, forms colorless crystals which are fairly soluble in water and are readily soluble in most organic solvents [23, p. 406].

Dimethachlor is produced by reaction of 2,6-dimethylaniline with α-chloroethylmethyl ether, followed by reaction with chloroacetyl chloride [61].

Dimethachlor is a selective soil herbicide used pre-emergence for the control of annual grasses and broad-leaved weeds in oilseed rape.
Trade Name. Teridox (Novartis).

Metazachlor [*67129-08-2*], 2-chloro-*N*-(pyrazol-1-ylmethyl)acet-2′,6′-xylidide, $C_{14}H_{16}ClN_3O$, M_r 277.8, *mp* 85 °C, consists of yellowish crystals which are moderately soluble in water and are readily soluble in acetone, chloroform, ethyl acetate, and ethanol [23, p. 801].

Metazachlor is produced by reaction of 2,6-dimethylaniline with formaldehyde, followed by treatment with chloroacetyl chloride, and then with potassium pyrazole [62].

Metazachlor is a selective herbicide used pre- and early post-emergence for the control of winter and annual grasses and broad-leaved weeds in a variety of crops.
Trade Name. Butisan S (BASF).

Metolachlor [*51218-45-2*], 2-chloro-*N*-(2-methoxy-1-methylethyl)aceto-*o*-toluidide, $C_{15}H_{22}ClNO_2$, M_r 283.8, *mp* −62.1 °C, *b*p 100 °C/0.001 mmHg, is a colorless to light tan liquid which is moderately soluble in water and is miscible with most organic solvents [23, p. 833].

Metolachlor is produced by reaction of 2-methyl-6-ethylanilin with 2-chloroisopropyl methyl ether, followed by treatment with chloroacetyl chloride [63].

Metolachlor is a selective herbicide used pre-emergence and is incorporated pre-planting to control annual grasses and some broad-leaved weeds in many crops.
Trade Names. Dual, Dual S, Dual II (Novartis).

Pretilachlor [*51218-49-6*], 2-chloro-2′,6′-diethyl-*N*-(2-propoxyethyl)acetanilide, $C_{17}H_{26}ClNO_2$, M_r 311.9, *bp* 135 °C/0.001 mmHg, is a colorless liquid which is moderately soluble in water and readily soluble in benzene, hexane, methanol, and dichloromethane [23, p. 995].

Pretilachlor is produced by reaction of 2,6-diethylamine with α-chloroethyl propyl ether, followed by reaction with chloroacetyl chloride [64].

Pretilachlor is a selective herbicide effective against the main annual grasses, broad-leaved weeds, and sledges in transplanted and seeded rice.
Trade Names. Rifit, Sofit, Solnet (Novartis); Gorbo (Takeda); Sparkstar (Nissan), etc.

Propachlor [*1918-16-7*], 2-chloro-*N*-isopropylacetanilide, $C_{11}H_{14}ClNO$, M_r 211.7, *mp* 77 °C, is a light tan solid which is moderately soluble in water and readily soluble in most common organic solvents [23, p. 1013].

Propachlor is produced by reaction of aniline with 2-chloroisopropane, followed by treatment with chloroacetyl chloride [65].

Propachlor is a selective herbicide used pre-emergence and pre-planting-incorporated to control annual grasses and some broad-leaved weeds in a range of crops.

Trade Names. Ramrod (Monsanto); Albrass (Zeneca); Satecid (Sagrochem); Prolex (Makhteshim-Agon), etc.

Propisochlor [*86763-47-5*], 2-chloro-6′-ethyl-*N*-isopropoxymethylacetotoluidide, $C_{15}H_{22}ClNO_2$, M_r 283.8 *mp* 21.6 °C, *bp* 243 °C (decomp.), is a light brown to purple oil which is moderately soluble in water and soluble in most organic solvents [23, p. 1034].

Propisochlor is produced by reaction of 2-methyl-6-ethylaniline with chloromethyl isopropyl ether, followed by reaction with chloroacetyl chloride [66].

Propisochlor is a selective herbicide used pre-emergence and pre-planting-incorporated for the control of annual grasses and some broad-leaved weeds in maize, sunflowers, soya beans, potatoes, and peas.

Trade Name. Proponit (Nitrokémia).

Thenylchlor [*96491-05-3*], 2-chloro-*N*-(3-methoxy-2-thenyl)-2′,6′-dimethylacetanilide, $C_{16}H_{18}ClNO_2S$, M_r 323.8, *mp* 72 – 74 °C, is a colorless solid which is slightly soluble in water [23, p. 1182].

Thenylchlor is produced by reaction of 2,6-dimethylaniline with 3-methoxy-2-thenylmethyl chloride, followed by treatment with chloroacetyl chloride [67].

Thenylchlor is used pre-emergence for the control of annual grasses and broad-leaved weeds in paddy rice.

Trade Names. Kusamets, Onebest (Tokuyama).

7.8.4. 1,3,5-Triazines

Ametryn [*834-12-8*], N^2-ethyl-N^4-isopropyl-6-methylthio-1,3,5-triazine-2,4-diamine, $C_9H_{17}N_5S$, M_r 227.3, *mp* 84 – 86 °C, is a colorless powder which is moderately soluble in water and readily soluble in acetone, methanol, toluene, and *n*-octanol [23, p. 35].

Ametryn is produced by reaction of atrazine with methylmercaptan in the presence of sodium hydroxide [68].

Ametryn is a selective, systemic herbicide used pre- and post-emergence for the control of most annual grasses and broad-leaved weeds in pineapples, sugar cane, bananas, citrus fruit, maize, coffee, tea, etc, and in noncropland.

Trade Names. Evik, Gesapax (Novartis); Mebatryne (Rhône-Poulenc); Amesip (Sipcam), etc.

Atrazine [*1912-24-9*], 6-chloro-N^2-ethyl-N^4-isopropyl-1,3,5-triazine-2,4-diamine, $C_8H_{14}ClN_5$, M_r 215.7, *mp* 178.5 °C, forms a colorless powder which is moderately soluble in water, is fairly soluble in toluene and *n*-octanol, and is readily soluble in ethyl acetate, acetone, dichloromethane, and ethanol [23, p. 55].

Atrazine is produced by reaction of cyanuric chloride with one equivalent of ethylamine, followed by treatment with one equivalent of isopropylamine [69].

Atrazine is a selective, systemic herbicide used pre- and post-emergence to control annual broad-leaved weeds and annual grasses in maize, sorghum, sugar cane, etc, and in industrial weed control.
Trade Names. Atrex, Bicep, Gesaprim, Primagram, Primextra (Novartis); Mebazine (Rhône-Poulenc); Vectal (AgrEvo), etc.

Cyanazine [*21725-46-2*], 2-(4-chloro-6-ethylamino-1,3,5-triazin-2-ylamino)-2-methylpropiononitrile, $C_9H_{13}ClN_6$, M_r 240.7, *mp* 167.5 – 169 °C, is a colorless crystalline solid which is moderately soluble in water, fairly soluble in benzene and carbon tetrachloride, and readily soluble in chloroform, acetone, and ethanol [23, p. 280].

Cyanazine is produced by successive reaction of cyanuric chloride with ethylamine and 2-methyl-2-cyanopropylamine [70].

Cyanazine is a selective herbicide used pre-emergence for general weed control.
Trade Names. Bladex (Cyanamid, Du Pont); Cy-Pro (Griffin).

Desmetryn [*1014-69-3*], N^2-isopropyl-N^4-methyl-6-methylthio-1,3,5-triazine-2,4-diamine, $C_8H_{15}N_5S$, M_r 213.3, *mp* 84 – 86 °C, is a colorless powder which is moderately soluble in water and readily soluble in most organic solvents [23, p. 351].

Desmetryn is produced by reaction of cyanuric chloride with, in turn, isopropylamine, methylamine, and methanethiol [69].

Desmetryn is a selective systemic herbicide used post-emergence for the control of fat-hen and other annual broad-leaved weeds and grasses in brassica, herbs, onions, leeks, and conifer seedbeds.

Trade Name. Semeron (Novartis).

Dimethametryn [*22936-75-0*], N^2-(1,2-dimethylpropyl)-N^4-ethyl-6-methylthio-1,3,5-triazine-2,4-diamine, $C_{11}H_{21}N_5S$, M_r 255.4, *mp* 65 °C, forms colorless crystals which are moderately soluble in water and readily soluble in acetone, dichloromethane, methanol, *n*-octanol, and toluene [23, p. 407].

Dimethametryn is produced by reaction of cyanuric chloride with ethylamine, followed by treatment with isobutylamine [71].

Dimethametryn is a selective herbicide used for the control of annual broad-leaved weeds in transplanted- and seeded rice.
Trade Names. Avirosan (Novartis); Sparkstar (Nissan).

Prometon [*1610-18-0*], N^2,N^4-diisopropyl-6-methoxy-1,3,5-triazine-2,4-diamine, $C_{10}H_{19}N_5O$, M_r 225.3, *mp* 91 – 92 °C, is a colorless powder which is moderately soluble in water and is readily soluble in benzene, methanol, acetone, dichloromethane, and toluene [23, p. 1010].

Prometon is produced by reaction of propazine with methanol in the presence of sodium hydroxide [68].

Prometon is a nonselective, systemic herbicide which is used to control most annual and many perennial broad-leaved weeds, grasses, and brush weeds on non-crop areas.

Trade Name. Pramitol (Novartis).

Prometryn [*7287-19-6*], N^2,N^4-di-isopropyl-6-methylthio-1,3,4-triazine-2,4-diamine, $C_{10}H_{19}N_5S$, M_r 214.4, *mp* 18 – 120 °C, is a colorless powder which is moderately soluble in water, fairly soluble in hexane, and readily soluble in acetone, ethanol, toluene, and *n*-octanol [23, p. 1011].

Prometryn is produced by reaction of propazine with methylmercaptan in the presence of sodium hydroxide, followed by treatment with dimethyl sulfate [68].

Prometryn is a selective, systemic herbicide used pre-emergence in cotton, sunflowers, peanuts, cereals, peas, and beans and used post-emergence in cotton, potatoes, carrots, celery, and leeks.

Trade Names. Caparol, Gesagard (Novartis); Cotton-Pro (Griffin); Efmetryn (Efthymiadis), etc.

Propazine [*139-40-2*], 6-chloro-N^2,N^4-diisopropyl-1,3,5-triazine-2,4-diamine, $C_9H_{16}ClN_5$, M_r 129.7, *mp* 212 – 214 °C, is a colorless powder which is slightly soluble in water and fairly soluble in benzene, toluene, diethyl ether, and carbon tetrachloride [23, p. 1024].

Propazine is produced by the reaction between cyanuric chloride and two equivalents of isopropylamine [72].

Propazine is a selective, systemic herbicide used pre-planting and pre-emergence for the control of grasses and broad-leaved weeds in sorghum and umbelliferous crops.

Trade Names. Gesamil, Milogard (Novartis); Milo-Pro (Griffin); etc.

Simazine [*122-34-9*], 6-chloro-N^2,N^4-diethyl-1,3,5-triazine-2,4-diamine, $C_7H_{12}ClN_5$, M_r 201.7, *mp*225 – 227 °C, is a colorless powder which is slightly soluble in water, *n*-hexane and is moderately soluble in ethanol, acetone, toluene, and *n*-octanol [23, p. 1106].

Simazine is produced by reaction of cyanuric chloride with two equivalents of ethylamine [73].

Simazine is a selective, systemic herbicide used for the control of most germinating annual grasses and broad-leaved weeds in many crops.

Trade Names. Caliber, Gesatop, Princep, Princep Caliber (Novartis); Amizina (Sipcam); Sanasim (Sanachem), etc.

Simetryn [*1014-70-6*], N^2,N^4-diethyl-6-methylthio-1,3,5-triazine-2,4-diamine, $C_8H_{15}N_5S$, M_r 213.3, *mp* 82 – 83 °C, consists of colorless crystals which are moderately soluble in water, readily soluble in methanol, acetone, and toluene, and fairly soluble in *n*-hexane [23, p. 1108].

Simetryn is produced by reaction between simazine and methanethiol [68].

Simetryn is a selective herbicide used in combination with thiobencarb to control broad-leaved weeds in rice.

Trade Name. Gy-bon (Novartis, Nihon Nohyaku).

Terbumeton [*33693-04-8*], N^2-*tert*-butyl-N^4-ethyl-6-methoxy-1,3,5-triazine-2,4-diamine, $C_{10}H_{19}N_5O$, M_r 225.3, *mp* 123 – 124 °C, forms

colorless crystals which are moderately soluble in water and are readily soluble in acetone, toluene, methanol, dichloromethane, and *n*-hexane [23, p. 1167].

Terbumeton is produced by reaction of 2-*tert*-butylamino-4-chloro-6-ethylamino-*s*-triazine with methanol and sodium hydroxide [68].

Terbumeton is a selective herbicide used to control annual and perennial grasses and broad-leaved weeds in citrus orchards. In combination with terbuthylazine, it is used for the herbicidal control in vineyards, apple- and citrus orchards, and in forestry.
Trade Name. Caragard (Novartis).

Terbuthylazine [*5915-41-3*], N^2-*tert*-butyl-6-chloro-N^4-ethyl-1,3,5-triazine-2,4-diamine, $C_9H_{16}ClN_5$, M_r 229.7, *mp* 177 – 179 °C, is a colorless powder which is slightly soluble in water and fairly soluble in acetone, ethanol, and *n*-octanol. [23, p. 1168].

Terbuthylazine is produced by reaction of cyanuric chloride with *tert*-butylamine, followed by treatment with ethylamine in the presence of sodium hydroxide [74].

Terbuthylazine is a broad-spectrum herbicide used pre- and post-emergence for the control of weeds in many crops, in forestry, and in tree nurseries.
Trade Names. Gardoprim, Folar, Topogard (Novartis); Tyllanex (Makhteshim-Agan), etc.

Terbutryn [*886-50-0*], N^2-*tert*-butyl-N^4-ethyl-6-methylthio-1,3,5-triazine-2,4-diamine, $C_{10}H_{19}N_5S$, M_r 241.4, *mp* 104 – 105 °C, is a colorless powder which is slightly soluble in water and is readily soluble in many organic solvents. [23, p. 1170].

Terbutryn is produced by reaction of 2-chloro-4-ethylamino-4,6-butylamino-1,3,5-triazine with methyl mercaptan in the presence of sodium hydroxide [68].

Terbutryn is a selective herbicide used pre-emergence as well as post-emergence to control black grass and annual meadow grass in winter cereals, sugar cane, sunflowers, and other crops.
Trade Names. Igran (Novartis); Terbutrex (Makhteshim-Agan), etc.

Trietazine [*1912-26-1*], 6-chloro-N^2,N^2,N^4-triethyl-1,3,5-triazine-2,4-diamine, $C_9H_{16}ClN_5$, M_r 229.7, *mp* 102 – 103 °C, consists of colorless crystals which are moderately soluble in water and are readily soluble in acetone, benzene, chloroform, dioxane, and ethanol [23, p. 1243].

Trietazine is produced by reaction of trichloro-1,3,5-triazine with ethylamine, followed by treatment with diethylamine [75].

Trietazine is a selective herbicide, used for weed control in combination with linuron in potatoes, in combination with simazine in peas, and in combination with terbutryn in potatoes, peas, and field beans.
Trade Names. Remtal (AgrEvo); Aventox (DowElanco).

7.8.5. Ureas

Chlorbromuron [*13360-45-7*], (4-bromo-3-chlorophenyl)-1-methoxy-1-methylurea, $C_9H_{10}BrClN_2O_2$, M_r 293.5, *mp* 95 – 97 °C, is a colorless powder which is moderately soluble in water and is readily soluble in acetone, dichloromethane, hexane, benzene, and isopropyl alcohol [23, p. 204].

Chlorbromuron is made by bromination of *N*-(3-chlorophenyl)-*N′*-methoxy-*N′*-methyl urea [76].

Chlorbromuron is a selective herbicide used pre-emergence on carrots, peas, potatoes, sugar cane, and sunflowers; it is used post-emergence on carrots and transplanted celery.
Trade Name. Maloran (Novartis).

Chlorotoluron [*15545-48-9*], 3-(3-chloro-*p*-tolyl)-1,1-dimethylurea, $C_{10}H_{13}ClN_2O$, M_r 212.7, *mp* 148.1 °C, is a colorless powder which is moderately soluble in water and hexane and is fairly soluble in acetone, dichloromethane, ethanol, *n*-octanol, and ethyl acetate [23, p. 229].

Chlorotoluron is produced by reaction of 3-chloro-*p*-tolyl isocyanate with dimethylamine [77].

Chlorotoluron is a selective herbicide used as a residual soil-acting herbicide and as a contact foliar spray against many broad-leaved weeds and grass weeds of winter cereals.
Trade Names. Dicuran (Novartis); Cekutoluron (Cequisa); Chlortophyt (Agriohar), etc.

Daimuron [*42609-52-9*], 1-(1-methyl-1-phenylethyl)-3-*p*-tolylurea, $C_{17}H_{20}N_2O$, M_r 268.4, *mp* 203 °C, forms colorless needles which are sparingly soluble in water and hexane and are fairly soluble in acetone and methanol [23, p. 330].

Daimuron is produced by reaction of isopropylaniline with *p*-toluene isocyanate [78].

Daimuron is a selective herbicide used pre- and post-emergence to control cyperaceous weeds and annual grass weeds in paddy rice.
Trade Name. Showrone (SDS Biotech).

Dimefuron [*34205-21-5*], [4-(5-*tert*-butyl-2,3-dihydro-2-oxo-1,3,4-oxadiazol-3-yl)-3-chlorophenyl]-1,1-dimethylurea, $C_{15}H_{19}ClN_4O_3$, M_r 338.8, *mp* 193 °C, consists of colorless crystals which are slightly soluble in water, benzene, toluene, and xylene, are readily soluble in chloroform, and are moderately soluble in acetone, acetonitrile, and ethanol [23, p. 403].

Dimefuron is produced by the reduction of the nitro group in 4-(5-*tert*-butyl-2,5-dihydro-2-oxo-1-oxadiazol-3-yl)-3-chloronitrobenzene, followed by treatment with phosgene and then with dimethylamine [79].

Dimefuron is a selective herbicide used pre- and post-emergence against different annual broad-leaved weeds in many crops.
Trade Names. Pradone (Rhône-Poulenc); Scorpion (AgrEvo).

Diuron [*330-54-1*], 3-(3,4-dichlorophenyl)-1,1-dimethylurea, $C_9H_{10}Cl_2N_2O$, M_r 233.1, *mp* 158 – 159 °C, forms colorless crystals which are slightly soluble in water, are sparingly soluble in hydrocarbons, and are fairly soluble in acetone, and benzene [23, p. 443].

Diuron is produced by reaction of 3,4-dichlorophenyl isocyanate with dimethylamine [80].

Diuron is a systemic herbicide which is used to control weeds and mosses on noncrop areas and is used for selective control of germinating grass and broad-leaved weeds in many crops.

Trade Names. Karmex (Du Pont); Seduron (Rhône-Poulenc); Unidron (Unicrop); Toterbane (Diachem), etc.

Fenuron [*101-42-8*], 1,1-dimethyl-3-phenylurea, $C_9H_{12}N_2O$, M_r 164.2, *mp* 133 – 134 °C, consists of colorless crystals which are fairly soluble in water, diethyl ether, acetone, and benzene and are readily soluble in ethanol, acetone, and chloroform [23, p. 537].

Fenuron is produced by reaction of phenyl isocyanate with dimethylamine [80].

Fenuron is a nonselective, systemic herbicide used for the control of woody plants and deep-rooted perennial weeds on noncropland.

Trade Name. Croptex Chrome (Hortichem), etc.

Fluometuron [*2164-17-2*], 1,1-dimethyl-3-(α,α,α-trifluoro-*m*-tolyl)urea, $C_{10}H_{11}F_3N_2O$, M_r 232.3, *mp* 163 – 164 °C, consists of colorless crystals which are moderately soluble in water and hexane, are fairly soluble in dichloromethane and *n*-octanol, and are readily soluble in methanol and acetone [23, p. 578].

Fluometuron is produced by reaction of 3-trifluoromethylphenyl isocyanate with dimethylamine [81].

Fluometuron is a selective, systemic herbicide used to control annual broad-leaved weeds and grasses in cotton and soya beans.

Trade Names. Cotogard, Cotoran (Novartis); Meturon (Griffin), etc.

Isoproturon [*34123-59-6*], 3-(4-isopropylphenyl)-1,1-dimethylurea, $C_{12}H_{18}N_2O$, M_r 206.3, *mp* 158 °C, consists of colorless crystals which are moderately soluble in water and hexane, are fairly soluble in benzene and xylene, and are readily soluble in methanol, dichloromethane, and acetone [23, p. 732].

Isoproturon is produced by reaction of 4-isopropylphenyl isocyanate with dimethylamine [82].

Isoproturon is a selective, systemic herbicide used post-emergence for the control of annual grasses and many annual broad-leaved weeds in spring and winter wheat, spring and winter barley, winter rye, and titricale.

Trade Names. Panron (Sanonda), Alon, Arelon (AgrEvo); Strong (Rhône-Poulenc); Pasport (Searle India), etc.

Isouron [*55861-78-4*], 3-(5-*tert*-butylisoxazol-3-yl)-1,1-dimethylurea, $C_{10}H_{17}N_3O_2$, M_r 211.3, *mp* 119 – 120 °C, consists of colorless crystals which are moderately soluble in water and readily soluble in ethanol, acetone, and xylene [23, p. 734].

Isouron is produced by reaction of 3-*tert*-butyl-isoxazol-2-yl isocyanate with dimethylamine [83].

Isouron is a selective, systemic herbicide used pre- and post-emergence for the control of broad-leaved weeds and grasses in sugar cane and pineapples.

Trade Name. Isoxyl (Shionogi).

Linuron [*330-55-2*], 3-(3,4-dichlorophenyl)-1-methoxy-1-methylurea, $C_9H_{10}Cl_2N_2O_2$, M_r 249.1, *mp* 93 – 95 °C, forms colorless crystals which are moderately soluble in water and aromatic hydrocarbons, are sparingly soluble in aliphatic hydrocarbons, and are readily soluble in acetone, ethanol, chloroform, and dimethylformamide [23, p. 751].

Linuron is produced by reaction of 3,4-dichlorophenyl isocyanate with methoxymethylamine [84].

Linuron is a selective, systemic herbicide used pre- and post-emergence to control annual grasses and broad-leaved weeds, and some seedlings of perennial weeds in a wide range of crops.

Trade Names. Lorox (Du Pont); Afalon (AgrEvo); Linex (Griffin); Siolcid (Siapa); etc.

Methabenzthiazuron [*1891-97-9*], 1-(1,3-benzothiazol-2-yl)-1,3-dimethylurea, $C_{10}H_{11}N_3OS$, M_r 221.3, *mp* 119 – 121 °C, consists of colorless crystals which are moderately soluble in water, fairly soluble in methanol, isopropyl alcohol, and toluene, and readily soluble in acetone, dimethylformamide, and dichloromethane [23, p. 805].

Methabenzthiazuron is produced by reaction of 2-methylaminobenzothiazole with methylisocyanate [85].

Methabenzthiazuron is a selective herbicide used to control a broad spectrum of broad-leaved weeds and grasses in cereals, legumes, maize, garlic, and onions.

Trade Name. Tribunil (Bayer).

Metobenzuron [*111578-32-6*], (±)-1-methoxy-3-[4-(2-methoxy-2,4,4-trimethylchroman-7-yloxy)phenyl]-1-methylurea, $C_{22}H_{28}N_2O_5$, M_r 40.5, *mp* 101.0 – 102.5 °C, is a colorless powder which is sparingly soluble in water [23, p. 830].

Metobenzuron is produced by reaction of 2-(2-methoxy-2,4,4-trimethylchroman-7-yloxy)phenyl isocyanate with dimethylamine [86].

Metobenzuron is a selective herbicide used post-emergence to control a wide range of broad-leaved weeds in maize.

Trade Name. To be announced (Mitsui).

Metobromuron [*3060-89-7*], 3-(4-bromophenyl)-1-methoxy-1-methylurea, $C_9H_{11}BrN_2O_2$, M_r 259.1, *mp* 95.5 – 96 °C, consists of colorless crystals which are moderately soluble in water, fairly soluble in hexane, and readily soluble in acetone, dichloromethane, methanol, toluene, octanol, and chloroform [23, p. 831].

Metobromuron is produced by bromination of 3-phenyl-1-methoxy-1-methylurea [87].

Metobromuron is a selective, systemic herbicide used pre-emergence for the control of annual broad-leaved weeds and grasses in beans, potatoes, tomatoes, tobacco, soya beans, maize, artichokes, and sugar beet.

Trade Names. Patoran (Novartis); Paltonex (Makhteshim-Agan), etc.

Metoxuron [*19937-59-8*], 3-(3-chloro-4-methoxyphenyl)-1,1-dimethylurea, $C_{10}H_{13}ClN_2O_2$, M_r 228.7, *mp* 126 – 127 °C, forms colorless crystals which are moderately soluble in water, diethyl ether, benzene, and toluene, are practically insoluble in petroleum ether, and are readily soluble in acetone, cyclohexanone, acetonitrile, and hot ethanol [23, p. 838].

Metoxuron is produced by reaction of 3-chloro-4-methoxyphenyl isocyanate with dimethylamine [76].

Metoxuron is a selective herbicide used pre- and post-emergence for the control of some grasses and annual broad-leaved weeds in winter wheat, winter barley, winter rye, and some varieties of spring wheat.
Trade Names. Dasonex (Cyanamid); Deftor (AgrEvo); Sulerex (Siagra), etc.

Monolinuron [*1746-81-2*], 3-(4-chlorophenyl)-1-methoxy-1-methylurea, $C_9H_{11}ClN_2O_2$, M_r 214.6, *mp* 80 – 83 °C, consists of colorless crystals which are moderately soluble in water, and are readily soluble in common organic solvents [23, p. 851].

Monolinuron is produced by reaction of 4-chlorophenyl isocyanate with *N*-methylhydroxylamine, followed by treatment with dimethyl sulfate [88].

Monolinuron is a selective, systemic herbicide used pre- and post-emergence to control broad-leaved weeds and some annual grasses in vegetables, ornamental shrubs, and trees.
Trade Names. Arresin, Aresin (AgrEvo).

Neburon [*555-37-3*], 1-butyl-3-(3,4-dichlorophenyl)-1-methylurea, $C_{12}H_{16}Cl_2N_2O$, M_r 275.2, *mp* 102 – 103 °C, forms colorless crystals which are slightly soluble in water and are sparingly soluble in hydrocarbons [23, p. 872].

Neburon is produced by reaction of 3,4-dichlorophenyl isocyanate with *N*-methylbutylamine [80].

Neburon is a selective herbicide used pre-emergence for the control of broad-leaved weeds and grasses in beans, peas, cereals, beet, ornamentals, and in forestry.
Trade Names. Granurex (Rhône-Poulenc); Neburex (Makhteshim-Agan).

Siduron [*1882-49-6*], 1-(2-methylcyclohexyl)-3-phenylurea, $C_{14}H_{20}N_2O$, M_r 232.3, *mp* 133 – 138 °C, consists of colorless crystals which are moderately soluble in water and readily soluble in dimethylformamide, ethanol, and dichloromethane [23, p. 1103].

Siduron is produced by reaction of phenyl isocyanate with 2-methylcyclohexylamine [89].

Siduron is a selective herbicide used pre-emergence to control Digitaria sp. and annual grass weeds in newly seeded grass or established turf.
Trade Name. Tupersan (Gowan).

Tebuthiuron [*34014-18-1*], 1-(5-*tert*-butyl-1,3,4-thiadiazol-2-yl)-1,3-dimethylurea, $C_9H_{16}N_4OS$, M_r 228.3, *mp* 161.5 – 164 °C (decomp.), forms colorless crystals which are fairly soluble in water, benzene, and hexane, and are readily soluble in acetonitrile, acetone, methanol, and chloroform [23, p. 1153].

Tebuthiuron is produced by reaction of 5-*tert*-butyl-2-*N*-methyl isocyanate-1,3,4-thiadiazole with methylamine [90].

Tebuthiuron is a systemic broad-spectrum soil herbicide used for the control of herbaceous- and woody plants, as well as broad-leaved weeds. It is also used for the control of total vegetation in non-crop areas, undesirable plants in pasture and rangeland, and broad-leaved weeds and grass in sugar cane.
Trade Names. Spike (DowElanco); Bushwacker (Rhône-Poulenc); Tebusan (Sanachem).

7.8.6. 2,6-Dinitroanilines

Benfluralin [*1861-40-1*], *N*-butyl-*N*-ethyltextitα,α,α-trifluoro-2,6-dinitro-*p*-toluidine, $C_{13}H_{16}F_3N_3O_4$, M_r 335.3, *mp* 121 – 122 °C,

forms yellow-orange crystals which are practically insoluble in water, fairly soluble in hexane and methanol, and readily soluble in acetone, ethyl acetate, dichloromethane, chloroform, toluene, and acetonitrile [23, p. 94].

Benfluralin is produced by nitration of 4-chloro-trifluorotoluene, followed by treatment with *N*-ethylbutylamine [91].

Benfluralin is a selective soil herbicide that is incorporated pre-emergence in the soil to control annual grasses and some annual broad-leaved weeds in peanuts, lettuce, cucumbers, chicory, endive, field beans, French beans, etc.
Trade Names. Balan, Team, XL-2G (DowElanco); Benefex (Makhteshim-Agan).

Butralin [*33629-47-9*], *N-sec*-butyl-4-*tert*-butyl-2,6-dinitroaniline, $C_{14}H_{21}N_3O_4$, M_r 295.3, *mp* 61 °C, forms yellow-orange crystals which are sparingly soluble in water and readily soluble in methanol and hexane [23, p. 165].

Butralin is produced by nitration of *tert*-butyl-4-chlorobenzene and subsequent reaction with *sec*-butylamine [92].

Butralin is a selective herbicide used pre-emergence for the control of annual broad-leaved weeds and grasses in cotton, soya beans, rice, barley, beans, vines, ornamentals, orchards of fruit and nut trees, etc.
Trade Names. Amexine (CFPI), Tamex (CFPI, Rhône-Poulenc).

Dinitramine [*29091-05-2*], *N,N*-diethyl-2,6-dinitro-4-trifluoromethyl-*m*-phenylenediamine, $C_{11}H_{13}F_3N_4O_4$, M_r 322.2, *mp* 98 – 99 °C, consists of yellow crystals which are sparingly soluble in water, moderately soluble in *n*-hexane, and readily soluble in acetone, chloroform, benzene, xylene, and ethanol [23, p. 423].

Dinitramine is produced by reaction of 2-amino-3,5-dinitro-4-chlorotrifluorotoluene with diethylamine [93].

Dinitramine is a selective soil herbicide used pre-planting and soil-incorporated for the control of many grass- and broad-leaved weeds in cotton, vegetables, sunflowers, transplanted tomatoes, aubergines, etc.
Trade Name. Cobex (Wacker).

Ethalfluralin [*55283-68-6*], N-ethyl-α,α,α-trifluoro-*N*-(2-methylallyl)-2,6-dinitro-*p*-toluidine, $C_{13}H_{14}F_3N_3O_4$, M_r 333.3, *mp* 55 – 56 °C, forms yellow-orange crystals which are sparingly soluble in water and are fairly soluble in acetone, acetonitrile, benzene, chloroform, dichloromethane, xylene, and methanol [23, p. 473].

Ethalfluralin is produced by reaction of 2,6-dinitro-4-trifluoromethylchlorobenzene with *N*-ethylmethylallylamine [94].

Ethalfluralin is a selective soil herbicide used pre-planting and soil-incorporated for the control of most germinating annual grasses and broad-leaved weeds in cotton, soya beans, dry beans, lentils, peanuts, etc.
Trade Names. Sonalan, Edge (DowElanco).

Fluchloralin [*33245-39-5*], *N*-(2-chloroethyl)-2,6-dinitro-*N*-propyl-4-trifluoromethylaniline, $C_{12}H_{13}ClF_3N_3O_4$, M_r 355.7, *mp* 42 – 43 °C, is a yellow-orange solid which is sparingly soluble in water and readily soluble in acetone, benzene, chloroform, diethyl ether, ethyl acetate, cyclohexane, and ethanol [23, p. 560].

Fluchloralin is produced by reaction of 2,6-dinitro-4-trifluoromethylbenzene with *N*-chloroethylpropylamine [95].

Fluchloralin is used pre- and post-emergence and soil-incorporated for the control of annual grasses and some broad-leaved weeds in several crops.

Trade Name. Baselin (BASF).

Oryzalin [*19044-88-3*], 3,5-dinitro-N^4,N^4-dipropylsulfanilamide, $C_{12}H_{18}N_4O_6S$, M_r 346.4, *mp* 141 – 142 °C, forms yellow-orange crystals which are moderately soluble in water, fairly soluble in benzene and xylene, and readily soluble in acetone, acetonitrile, methanol, and dichloromethane, [23, p. 900].

Oryzalin is produced by reaction of 4-dipropylamino-3,5-dinitrobenzene sulfonylchloride with ammonium hydroxide [96].

Oryzalin is a selective herbicide used pre-emergence for the control of many annual grasses and broad-leaved weeds in a variety of crops and in noncrop areas.

Trade Name. Surflan (DowElanco).

Pendimethalin [*40487-42-1*], *N*-(1-ethylpropyl)-2,6-dinitro-3,4-xylidine, $C_{13}H_{19}N_3O_4$, M_r 281.3, *mp* 54 – 58 °C, consists of yellow-orange crystals which are slightly soluble in water and readily soluble in many organic solvents [23, p. 937].

Pendimethalin is produced by reaction of 2,6-dichloro-4,5-dimethyl chlorobenzene with 1-ethylpropylamine [97].

Pendimethalin is a selective herbicide used pre-planting incorporated, and pre- and post-emergence for the control of most annual grasses and many broad-leaved weeds in a number of crops.

Trade Names. Herbadox, Prowl, Stomp (Cyanamid).

Prodiamine [*29091-21-2*], 5-dipropylamino-α,α,α-trifluoro-4,6-dinitro-*o*-toluidine, $C_{13}H_{17}F_3N_4O_4$, M_r 350.3, *mp* 122.5 – 124 °C, forms yellow crystals which are practically insoluble in water, are fairly soluble in acetonitrile, benzene, ethanol, hexane, and xylene, and are readily soluble in acetone, and chloroform [23, p. 1004].

Prodiamine is produced by reaction of 2-amino-3,5-dinitro-4-chloro-α,α,α-trifluorotoluene with dipropylamine [98].

Prodiamine is a selective herbicide used pre-planting or pre-emergence for the control of annual grasses and broad-leaved weeds in cotton, nonbearing fruit trees, vines, nuts, ornamentals, turf, etc.

Trade Names. Barricade, Kusablock (Novartis).

Trifluralin [*1582-09-8*], α,α,α-trifluoro-2,6-dinitro-*N*,*N*-dipropyl-*p*-toluidine, $C_{13}H_{16}F_3N_3O_4$, M_r 335.3, *mp* 48.5 – 49 °C, forms yellow-orange crystals which are sparingly soluble in water, fairly soluble in methanol and hexane, and readily soluble in acetone, chloroform, acetonitrile, toluene, and ethyl acetate [23, p. 1248].

Trifluralin is produced by nitration of 4-chloro-trifluorotoluene, followed by treatment with dipropylamine [99].

Trifluralin is a selective soil herbicide used pre-emergence for the control of annual grasses and broad-leaved weeds in many crops.

Trade Names. Treflan (DowElanco); Commerce (FMC); Zeltoxone (Zeneca); Tri-4 (Cyanamid); Trifsan (Sanachem); Trilin (Griffin), Triplen (Sipcam), etc.

7.8.7. Imidazolinones

Imazamethabenz-methyl [*81405-85-8*], a mixture of (±)-6-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)-*m*-toluate and (±)-2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)-*p*-toluate, $C_{16}H_{20}N_2O_3$, M_r 288.3, *mp* 113 – 153 °C, is a fine to lumpy powder which is moderately soluble in water, *n*-hexane, and *n*-heptane, and is readily soluble in acetone, dimethyl sulfoxide, isopropyl alcohol, methanol, and toluene [23, p. 694].

Imazamethabenz-methyl is produced by reaction of 3,4-(4,5)-dicarboxymethyltoluene with 2-aminoamide-3-methylbutane in the presence of two equivalents of potassium *tert*-butoxide [100].

Imazamethabenz-methyl is a selective, systemic herbicide which is effective post-emergence against some broad-leaved and some dicotyledonous weeds in wheat, barley, rye, and sunflowers.

Trade Names. Assert, Dagger (Cyanamid).

Imazamox [*114311-32-9*], (*R*,*S*)-2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)-5-methoxymethylnicotinic acid, $C_{15}H_{19}N_3O_4$, M_r 305.3, *mp* 166.0 – 166.7 °C, forms colorless crystals which are fairly soluble in acetone [23, p. 696].

Imazamox is produced by reaction of 2,3-dicarboxymethyl-5-methoxymethylpyridine with 2-aminoamide-3-methylbutane in the presence of two equivalents of potassium *tert*-butoxide [100].

Imazamox is a selective herbicide under development which is to be used post-emergence for weed control in soya beans and other vegetables grown in rotation with sugar beet and other crops.

Trade Names. Odyssey, , Sweeper (Cyanamid).

Imazapic (AC 263 222) [*104098-48-8*], (*R*,*S*)-2-(4,5-dihydro-4-isopropyl-4-methyl-5-oxoimidazol-2-yl)-5-methylnicotinic acid, $C_{14}H_{17}N_3O_3$, M_r 275.3, *mp* 204 – 206 °C, is a tan powder which is moderately soluble in water and acetone [23, p. 5].

Imazapic is produced by reaction of 2,3-dicarboxymethyl-5-methylpyridine with 2-aminoamide-3-methylbutane in the presence of two equivalents of *tert*-butoxide [101].

Imazapic is a herbicide used early post-emergence for the control of a wide range of weeds in peanuts.

Trade Name. Cadre (Cyanamid).

Imazapyr [*81334-34-1*], 2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)nicotinic acid, $C_{13}H_{15}N_3O_3$, M_r 261.3, *mp* 169 – 173 °C, is a colorless to tan powder which is fairly soluble in water, acetone, methanol, dichloromethane, and dimethylformamide, slightly soluble in benzene, and moderately soluble in toluene [23, p. 697].

Imazapyr is produced by reaction of 2,3-dicarboxymethylpyridine with 2-aminoamide-3-methylbutane in the presence of two equivalents of *tert*-butoxide [102].

Imazapyr is a nonselective, systemic herbicide used pre- and post-emergence for the control of annual and perennial grasses, sledges, broad-leaved weeds, many bushes, and deciduous tree species on noncrop areas.

Imazaquin [*81335-37-7*], (*R*,*S*)-2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)quinoline-2-carboxylic acid, $C_{17}H_{17}N_3O_3$, M_r 311.3, *mp* 219 – 224 °C (decomp.), is a tan solid which is moderately soluble in water and toluene, and is fairly soluble in dimethylformamide, dimethyl sulfoxide, and dichloromethane [23, p. 699].

Imazaquin is produced by reaction of 2,3-dicarboxymethylquiniline with 2-aminoamide-3-methylbutane in the presence of two equivalents of *tert*-butoxide [102].

Imazaquin is a selective, systemic herbicide used pre-planting, pre-emergence, and early post-emergence to control broad-leaved weeds in soya beans.

Trade Name. Scepter (Cyanamid).

Imazethapyr [*81335-77-5*], (*R*,*S*)-5-ethyl-2-(4-isopropyl-4-methyl-5-oxo-2-imidazolin-2-yl)nicotinic acid, $C_{15}H_{19}N_3O_3$, M_r 289.2, *mp* 169 – 173 °C, forms colorless crystals which are fairly soluble in water, toluene and heptane, and are readily soluble in acetone, methanol, dichloromethane, and dimethyl sulfoxide [23, p. 701].

Imazethapyr is produced by reaction of 2,3-dicarboxymethyl-5-ethylpyridine with 2-aminoamide-3-methylbutane in the presence of two equivalents of *tert*-butoxide [102].

Imazethapyr is a systemic herbicide used pre-plant-incorporated, pre- and post-emergence for the control of many annual and perennial grasses and broad-leaved weeds in soya beans and other leguminous crops.

Trade Names. Hammer, Overtop, Pivot, Pursuit (Cyanamid).

7.8.8. Alkanoic Acids

Clomeprop [*84496-56-0*], (*R*,*S*)-2-(2,4-dichloro-*m*-tolyloxy)propionanilide, $C_{16}H_{15}Cl_2NO_2$, M_r 324.2, *mp* 146 – 147 °C, consists of colorless crystals which are sparingly soluble in water and are fairly soluble in xylene, acetone, cyclohexane, and dimethylformamide [23, p. 258].

Clomeprop is produced by reaction of the potassium salt of 2,4-dichloro-3-methylphenol with 2-chloropropionanilide [103].

Clomeprop is an auxin-type herbicide used pre- to early post-emergence to control broad-leaved weeds and cyperaceous weeds in paddy rice.

Trade Name. Yukahope (Mitsubishi).

2,4-D [*94-75-7*], (2,4-di-chlorophenoxy)acetic acid, $C_8H_6Cl_2O_3$, M_r 221.0, *mp* 140.5 °C, forms colorless crystals which are moderately soluble in water, heptane, toluene, and xylene, and are readily soluble in ethanol and diethyl ether [23, p. 323].

2,4-D is produced by interaction of 2,4-dichlorophenolate with monochloroacetic acid [104].

2,4-D is a selective, systemic herbicide, it acts as a growth inhibitor, and is used post-emergence for the control of annual and perennial weeds in many crops.

Trade Names. Ded-Weed (Uniroyal); Desormone (Rhône-Poulec); U46D (BASF); Weedtox (Aimco), etc.

Dalapon [*75-99-0*], 2,2-dichloropropionic acid, $C_3H_4Cl_2O_2$, M_r 143.0, *mp* 185 – 190 °C, is a colorless liquid. Its sodium salt is readily soluble in water, fairly soluble in ethanol and methanol, and moderately soluble in acetone [23, p. 331].

$CH_3CCl_2CO_2H$

Dalapon is produced by chlorination of propionic acid [105].

Dalapon is a selective, systemic herbicide, used as its sodium salt to control annual and perennial grasses on noncropland and in orchards.

Trade Names. Dalacide (Diachem); Diserbo Canali (Siapa), etc.

2,4-DB [*94-82-6*], 4-(2,4-dichlorophenoxy)butyric acid, $C_{10}H_{10}Cl_2O_3$, M_r 249.1, *mp* 117 – 119 °C, consists of colorless crystals which are moderately soluble in water, are readily soluble in acetone, ethanol, and diethyl ether, and are slightly soluble in benzene and toluene [23, p. 337].

2,4-DB is produced by reaction of 2,4-dichlorophenol with trimethylene chlorobromide, followed by reaction with sodium cyanide and hydrolysis of the resulting cyano compound to the acid [106].

2,4-DB is a selective, systemic, hormone-type herbicide used post-emergence for the control of many annual and perennial broad-leaved weeds in alfalfa, clovers, under-sown cereals, grassland, etc.

Trade Names. Embutox (Rhône-Poulenc); Butormone (Unicrop); Butoxone (Cedar), etc.

Dichlorprop [*7547-66-2*], (*R*,*S*)-2-(2,4-dichlorophenoxy)propionic acid, $C_9H_8Cl_2O_3$, M_r 235.1, *mp* 116 – 117.5 °C, forms colorless crystals which are moderately soluble in water and are readily soluble in acetone, isopropyl alcohol, benzene, toluene, and xylene [23, p. 368].

Dichlorprop is produced by reaction of 2-chloropropionic acid with 2,4-dichlorophenol [107].

Dichlorprop is a selective, systemic, hormone-type herbicide used post-emergence to control annual and perennial broad-leaved weeds in cereals and grassland, as well as for brush control on noncropland.

Trade Names. Weedone (Rhône-Poulenc); U46 DPC (BASF); Polymone (Unicrop), etc.

Dichlorprop-P [*15165-67-0*], (*R*)-2-(2,4-dichlorophenoxy)propionic acid, $C_9H_8Cl_2O_3$, M_r 235.1, *mp* 121 – 123 °C, forms colorless crystals which are moderately soluble in water, are readily soluble in acetone, ethanol, and ethyl acetate, and are fairly soluble in toluene [23, p. 370].

Dichlorprop-P is produced analogously to dichlorprop, but from the (+)-stereoisomer of propionic acid, obtained by fermentation [108].

Dichloprop-P is a selective, systemic, hormone-type herbicide used post-emergence for the control of various weed species.

Trade Name. (BASF).

Flupropanate [*756-09-2*], 2,2,3,3-tetrafluoropropionic acid [*22898-01-7*]. Its sodium salt, $C_3HF_4NaO_2$, M_r 168.0, *mp* 165 – 167 °C, consists of colorless crystals which are fairly soluble in water and sparingly soluble in nonpolar organic solvents [23, p. 585].

$F_2CHCF_2CO_2H$

Flupropanate is produced by oxidation of 2,2,3,3-tetrafluoropropanol with chromium trioxide [109].

Flupropanate is a systemic herbicide with low contact activity, which is used for the control of annual and perennial grasses in pastures and in uncultivated land.

Trade Name. Frenock (Daikin, Sankyo, Hodogaya, Zeneca, Sumitomo).

Fluroxypyr [*69377-81-7*], 4-amino-3,5-dichloro-6-fluoro-2-pyridyloxyacetic acid, $C_7H_5Cl_2FN_2O_3$, M_r 255.0, *mp* 232 – 233 °C, forms a colorless crystalline solid which is moderately soluble in water, dichloromethane, toluene, and xylene, and is fairly soluble in acetone, methanol, and diethyl ether [23, p. 597].

Fluroxypyr is produced by reaction of 4-amino-3,5-dichloro-2-(methylsulfonyl)pyridine with methylglycolate [110].

Fluroxypyr is applied as fluroxypyr-methyl [*81406-37-3*] and produces characteristic auxin-type responses. It is used post-emergence to control a number of broad-leaved weeds in all small grains, in orchards, and in plantations.

Trade Names. Starane (DowElanco); Herber (Barclay).

MCPA [*94-74-6*], (4-chloro-2-methylphenoxy)acetic acid, $C_9H_9ClO_3$, M_r 200.6, *mp* 119 – 120.5 °C, consists of colorless crystals which are moderately soluble in water, are fairly soluble in toluene, xylene, and heptane, and are readily soluble in ethanol and diethyl ether [23, p. 767].

MCPA is produced by chlorination of *o*-cresol and coupling with monochloroacetic acid [111].

MCPA is a selective, systemic, hormone-like herbicide used post-emergence for the control of annual and perennial broad-leaved weeds in cereals, vegetables, grassland turf, roadside verges, embankments, forestry, etc.

Trade Names. Agrotone (Marks); Meadowman (Barclay); Empel (Unicrop); Sanphen-M (Sanachem), etc.

MCPA-thioethyl [*25319-90-8*], *S*-ethyl 4-chloro-*o*-tolyloxythioacetate, $C_{11}H_{13}ClO_2S$, M_r 244.7, *mp* 41 – 42 °C, forms colorless needles which are moderately soluble in water and readily soluble in acetone, xylene, and hexane [23, p. 770].

MCPA-thioethyl is produced by reaction of ethylmercaptan with 4-chloro-2-methylphenoxymethylcarboxychloride [112].

MCPA-thioethyl is a selective, systemic, hormonelike herbicide used post-emergence to control annual and perennial broad-leaved and cyperaceous weeds in orchards, paddy rice, and cereals.

Trade Names. Fenobit, Herbit, Zero One (Hokko).

MCPB [*94-81-5*], 4-(4-chloro-*o*-tolyloxy)butyric acid, $C_{11}H_{13}ClO_3$, M_r 228.7, *mp* 100 °C, consists of colorless crystals which are moderately soluble in water, fairly soluble in toluene, and readily soluble in acetone, dichloromethane, ethanol, and hexane [23, p. 771].

MCPB is produced by chlorination of *o*-cresol and coupling with γ-chlorobutyric acid [113].

MCPB is used as a sodium salt [*6062-26-6*] and is a selective, systemic, hormone-type herbicide used post-emergence for the control of annual and perennial broad-leaved weeds in cereals, clovers, peas, peanuts, grasslands, and forestry.

Trade Name. Tropotox (Unicrop).

Mecoprop [*7085-19-0*], (*RS*)-2-(4-chlorotextito-tolyloxy)propionic acid, $C_{10}H_{11}ClO_3$, M_r 214.6, *mp* 94 – 95 °C, forms colorless crystals which are moderately soluble in water and readily soluble in acetone, diethyl ether, ethanol, ethyl acetate, and chloroform [23, p. 776].

Mecoprop is produced by chlorination of 4-chloro-*o*-cresol and coupling with 2-chloropropionic acid [113].

Mecoprop is a selective, systemic, hormone-like herbicide used post-emergence for the control of broad-leaved weeds in wheat, barley, oats, seed crops, grassland, etc.

Trade Names. Actril (Rhône-Poulenc); Propal (Unicrop); Propionyl (Agriphar), etc.

Mecoprop-P [*16484-77-8*], (*R*)-2-(4-chloro-*o*-tolyloxy)propionic acid, $C_{10}H_{11}ClO_3$, M_r 214.6, *mp* 94.6 – 96.2 °C, forms colorless crystals which are moderately soluble in water, are fairly soluble in hexane, and are readily soluble in acetone, diethyl ether, ethanol, dichloromethane, and toluene [23, p. 778].

Mecoprop-P is produced analogously to Mecoprop-P from the corresponding propionic acid stereoisomer [114].

Mecoprop-P is a selective, systemic, hormonelike herbicide used post-emergence for the control of broad-leaved weeds in wheat, barley, oats, seed crops, grassland, etc.

Trade Names. Duplosan KV (BASF); Optica (Marks).

Triclopyr [*55335-06-3*], 3,5,6-trichloro-2-pyridylacetic acid, $C_7H_4Cl_3NO_3$, M_r 256.5, mp. 150.5 °C, is a fluffy, colorless solid which is fairly soluble in water, hexane, toluene, and dichloromethane and is readily soluble in acetone, acetonitrile, methanol, and ethyl acetate [23, p. 1237].

Triclopyr is produced by reaction of 2,3,5,6-tetrachloropyridine with formaldehyde in dimethyl sulfoxide containing potassium cyanide, followed by hydrolysis of the cyano compound to the acid [115].

Triclopyr is a selective, systemic herbicide used for the control of woody plants, many broad-leaved weeds in grassland, uncultivated land, industrial areas, coniferous foresst, plantation crops, and rice fields.

Trade Name. Trident (Agriphar).

7.8.9. Triazoles

Amitrole [*61-82-5*], 1*H*-1,2,4-triazol-3-ylamine, $C_2H_4N_4$, M_r 84.1, *mp* 157 – 159 °C, consists of colorless crystals which are readily soluble in water, are moderately soluble in methanol, acetonitrile, and chloroform, are sparingly soluble in ethyl acetate, and are practically insoluble in ethyl acetate, diethyl ether, acetone, and nonpolar solvents [23, p. 40].

Amitrole is produced by condensation of formic acid with aminoguanidine [116].

Amitrole is a nonselective herbicide which inhibits the biosynthesis of chlorophyll and regrowth from buds. It is used for the total control of annual and perennial grasses and broad-leaved weeds around established fruit trees and bushes in orchards, in vineyards, and in many other applications.
Trade Names. Weedazal (Rhône-Poulenc, CFPI); Superzol (Productos OSA); Oriflam (CFPI), etc.

Azafenidin [*68049-83-2*], 2-(2,4-dichloro-5-prop-2-ynyloxyphenyl)-5,6,7,8-tetrahydro-1,2,4-triazolo[4,3-*a*]pyridin-3(2*H*)-one, $C_{15}H_{13}Cl_2N_3O_2$, M_r 338.2, *mp* 168 – 168.5 °C, forms a rust-colored solid which is sparingly soluble in water [23, p. 60].

Azafenidin is produced by reaction of *N*-(2-piperidyl)-*N′*-(2,4-dichloro-5-oxy-methylacetylene)hydrazone with methylchloroformate [117].

Azafenidin is an inhibitor of the biosynthesis of porphyrin. It is under development and will be used pre-emergence in citrus, grapes, sugar cane, and other perennial crops.
*Trade Name.*To be announced (Du Pont).

Chloransulam-methyl [*147150-35-4*], (its acid: [*159518-97-5*]), methyl 3-chloro-2-(5-ethoxy-7-fluoro[1,2,4]triazolo[1,5-*c*]pyrimidin-2-ylsulfonamido)benzoate, $C_{15}H_{13}ClFN_5O_5S$, M_r 429.8 [23, p. 265].

Chloransulam-methyl is produced by condensation of 5-oxyethyl-7-fluoro-1,2,4-triazolo[1,5-*c*]pyrimidine-2-sulfonyl chloride with 2-carboxymethyl-6-chloroaniline [118].

Chloransulam-methyl is a acetolactate-synthase inhibitor, and is used pre- and post-emergence for the control of broad-leaved weeds in soya beans.
Trade Name. First Rate (DowElanco).

7.8.10. Uracils

Bromacil [*314-40-9*], 5-bromo-3-*sec*-butyl-6-methyluracil, $C_9H_{13}BrN_2O_2$, M_r 261.1, *mp* 157.5 – 160 °C, consists of colorless crystals which are moderately soluble in water and are fairly soluble in ethanol, acetone, and xylene [23, p. 140].

Bromacil is produced by reaction of isopropyl isocyanate with methyl 3-aminocrotonate, followed by cyclization in sodium hydroxide at elevated temperature, and bromination in acetic acid [119].

Bromacil is used for the total control of weeds and brushes on noncropland, and also for the selective control of annual and perennial weeds and grasses in citrus and pineapple plantations.
Trade Names. Hyvar X, Hyvar X-L (Du Pont); Rokar XL (Siapa); Uragan (Makhteshim-Agan), etc.

Lenacil [*2164-08-1*], 3-cyclohexyl-1,5,6,7-tetrahydrocyclopentapyrimidine-2,4-(3*H*)-dione, $C_{13}H_{18}N_2O_8$, M_r 234.3, *mp* 315.6 – 316.8 °C, forms colorless to tan crystals which are slightly soluble in water and readily soluble in most organic solvents [23, p. 748].

Lenacil is produced by condensation of cyclohexylurea and ethyl 2-oxocyclopentane-1-carboxylate with phosphoric acid [120].

Lenacil is a selective, systemic herbicide used for the control of annual grasses and broad-leaved weeds in sugar cane, beet, fodder beet, sweet potatoes, etc., and in ornamental plants and shrubs.
Trade Names. Venzar (Du Pont); Adol (Gedeon Richter).

Terbacil [*5902-51-2*], 3-*tert*-butyl-5-chloro-6-methyluracil, $C_9H_{13}ClN_2O_2$, M_r 216.7, *mp* 175 – 177 °C, consists of colorless crystals which are moderately soluble in water and readily soluble in dimethylformamide, cyclohexanone, methyl isobutyl ketone, and butyl acetate [23, p. 1163].

Terbacil is produced by reaction of *tert*-butyl isocyanate with methyl 3-aminocrotonate, followed by cyclization and chlorination [120].

Terbacil is a selective herbicide used for the control of many annual and some perennial weeds in apples, citrus, peaches, and other crops.
Trade Names. Sinbar (Du Pont); Geonter (Chemol).

7.8.11. Pyridines

Clopyralid [*1702-17-6*], 3,6-dichloropyridine-2-carboxylic acid, $C_6H_3Cl_2NO_2$, M_r 192.0, *mp* 151 – 152 °C, forms colorless crystals which are fairly soluble in water, acetonitrile, methanol, and *n*-hexane [23, p. 260].

Clopyralid is produced by photochlorination of picoline, followed by further photochlorination and oxidation [121].

Clopyralid is a selective, systemic herbicide with auxin-type activity, used post-emergence for the control of many annual and perennial broad-leaved weeds in sugar beet, fodder beet, oilseed rape, maize, etc.
Trade Names. Cyranal (AgrEvo); Clio (Agriphar).

Diflufenican [*83164-33-4*], 2′,4′-difluoro-2-(α,α,α-trifluoro-*m*-tolyloxy)nicotinanilide, $C_{19}H_{11}F_7N_2O_2$, M_r 394.3, *mp* 159 – 161 °C, forms colorless crystals which are practically insoluble in water, but are soluble in most organic solvents [23, p. 397].

Diflufenican is produced by reaction of 2-(3-trifluoromethylphenoxy)nicotinic acid with 2,4-difluoroaniline and sulfonyl chloride [122].

Diflufenican is a carotenoid- and photosynthesis electron-flow inhibitor. It is a selective contact and residual herbicide used pre- and early post-emergence to control grass and broad-leaved weeds in autumn-sown wheat and barley.
Trade Names. Fenican, Javelin (Rhône-Poulenc).

Diflufenzopyr (BAS 654 00H) [*109293-97-2*], 2-{1-[4-(3,5-difluorophenyl)semicarbazono]ethyl}nicotinic acid, $C_{15}H_{12}F_2N_4O_3$, M_r 334.3, *mp* 155 °C, is a tan to colorless solid which is sparingly soluble in water [23, p. 81].

Diflufenzopyr is produced by reaction of 2-acetylnicotinic acid with 3,5-difluorobenzene-*N*-2-methylsemicarbazone in the presence of pyridyl tosylate [123].

Diflufenzopyr is a polar auxin-transport inhibitor. This systemic herbicide is used post-emergence to control annual broad-leaved and perennial weeds in maize. An initial commercialization of a mixture with dicamba is planned.
Trade Name. To be announced (BASF).

Dithiopyr [*97886-45-8*], *S,S′*-dimethyl-2-difluoromethyl-4-isobutyl-6-trifluoromethylpyrimidine-3,5-dicarbothioate, $C_{15}H_{16}F_5NO_2S_2$, M_r 401.4, *mp* 65 °C, consists of colorless crystals which are sparingly soluble in water [23, p. 442].

Dithiopyr is produced by dehydration of diethyl 2,6-dihydro-2-difluoromethyl-6-trifluoromethyl-4-(2-methylisopropyl) piperidine dicarboxylate, followed by hydrolysis of the pyridine dicarboxylate, and by treatment with sulfonyl chloride and methanol [124].

Dithiopyr is a cell-division inhibitor used pre- and early post-emergence to control annual grasses and broad-leaved weeds in turf, and annual grasses in rice.

Trade Names. Dictran, Dimension (Rohm & Haas).

Picloram [*1918-02-1*], 4-amino-3,5,6-trichloropyridine-2-carboxylic acid, $C_6H_3Cl_3N_2O_2$, M_r 241.5, *mp* 215 °C (decomp.), is a colorless powder which is moderately soluble in water, dichloromethane, benzene, and carbon disulfide, and is fairly soluble in acetone, ethanol, and diethyl ether [23, p. 977].

Picloram is produced from α-picoline by chlorination, followed by hydrolysis of the α-trichloropicoline derivative, and amidation [125].

Picloram is a selective, systemic herbicide used to control most annual and perennial broad-leaved weeds on grassland and noncrop areas.

Trade Name. Tordon (DowElanco).

Thiazopyr [*117718-60-2*], methyl 2-difluoromethyl-5-(4,5-dihydro-1,3-thiazol-2-yl)-4-isobutyl-6-trifluoromethylnicotinate, $C_{16}H_{17}F_5N_2O_2S$, M_r 396.4, *mp* 77.3 – 79.1, is a light tan crystalline solid which is moderately soluble in water, and readily soluble in acetone and hexane [23, p. 1185].

Thiazopyr is produced by amination of 3-chlorocarbonyl-5-carboxymethyl-4-(2-methylpropyl)-2-trifluoromethyl-6-difluoromethylpyridine with ethanolamine, followed by treatment with phosphorus oxytrichloride, and cyclization [126].

Thiazopyr inhibits cell division, and is used pre-emergence for the control of annual grasses and some broad-leaved weeds in tree fruit, vines, citrus, sugar cane, and pineapples.

Trade Name. Visor (Rohm & Haas).

7.8.12. Hydroxybenzonitriles

Bromofenoxim [*13181-17-4*], 3,5-dibromo-4-hydroxybenzaldehyde 2,4-dinitrophenyloxime, $C_{13}H_7Br_2N_3O_6$, M_r 461.0, *mp* 196 – 197 °C, forms cream-colored crystals which are sparingly soluble in water, are moderately soluble in hexane, isopropyl alcohol, and *n*-octanol, and are fairly soluble in acetone [23, p. 145].

Bromofenoxim is produced by reaction of 3,5-dibromoanisaldehyde oxime with 2,4-dinitrochlorobenzene in the presence of sodium ethoxide [127].

Bromofenoxim, a precursor of bromoxynil, is a selective contact herbicide used post-emergence to control many annual broad-leaved weeds in cereals, maize, grass-seed crops, on grassland, and newly seeded turf.

Trade Name. Faneron (Novartis).

Bromoxynil [*1689-84-5*], 3,5-dibromo-4-hydroxybenzonitrile, $C_7H_3Br_2NO_2$, M_r 276.9, *mp* 194 – 195 °C, forms a colorless solid which is sparingly soluble in water, is fairly soluble in methanol, ethanol, and benzene, and is readily soluble in dimethylformamide, tetrahydrofuran, and acetone [23, p. 149].

Bromoxynil is produced by reaction of sodium hypobromide with 4-hydroxybenzonitrile [128].

Bromoxynil is a selective contact herbicide used post-emergence to control annual broad-leaved weeds in cereals, maize, sorghum, onions, garlic, mint, turf, noncropland, etc.

Trade Names. Brominal, Buctril (Rhône-Poulenc); Bromox, Bromoxan (Sanachem); Kaleis (Novartis).

7.8.13. (Thio)Carbamates

Asulam [*3337-71-1*], (sodium salt: [*2302-17-2*]), sulfanilcarbamate, $C_8H_{10}N_2O_4S$, M_r 230.2, *mp* 142 – 144 °C, consists of colorless crystals which are fairly soluble in water, hydrocarbons, and chlorinated hydrocarbons, and are readily soluble in acetone, methanol, methyl ethyl ketone, and dimethylformamide [23, p. 53].

Asulam is produced by reaction of 4-aminobenzenesulfonamide, after protection of the amino group, with ethyl chloroformate in the presence of a base [129].

Asulam, a cell-division inhibitor, is a selective, systemic herbicide used for the control of annual and perennial grasses and broad-leaved weeds in a variety of crops, grassland, noncropland, and forestry.

Trade Names. Asulox (Rhône-Poulenc); Asilan (Shionogi); Sanulam (Sanchem), etc.

Butylate [*2008-41-5*], *S*-ethyl di-isobutylthiocarbamate, $C_{11}H_{23}NOS$, M_r 217.4, *bp* 137.5 – 138 °C/21 mmHg, is a colorless liquid which is moderately soluble in water and is miscible with common organic solvents [23, p. 170].

$[(CH_3)_2CHCH_2]_2NC(O)SCH_2CH_3$

Butylate is produced by reaction of diisobutylcarbamoyl chloride with ethylmercaptan [130].

Butylate, which inhibits lipid metabolism, is a selective, systemic herbicide used pre-planting and soil-incorporated for the control of annual grass weeds in maize, pineapples, etc.

Trade Names. Sutan Plus (Zeneca); Anelda (Sagrochem), etc.

Carbetamide [*16118-49-3*], (*R*)-1-(ethylcarbamoyl)ethyl carbanilate, $C_{12}H_{16}N_2O_3$, M_r 236.3, *mp* 119 °C, consists of colorless crystals which are fairly soluble in water, moderately soluble in cyclohexane, and readily soluble in acetone, ethanol, methanol, and dimethylformamide [23, p. 184].

Carbetamide is produced by condensation of phenyl isocyanate with *N*-ethyl lactamide [131].

Carbetamide, a cell-division inhibitor, is a selective herbicide used to control annual grasses and some broad-leaved weeds in clover, some vegetables, oilseed rape, vines, and fruit orchards.

Trade Name. Leguram (Rhône-Poulenc).

Chlorpropham [*101-21-3*], isopropyl 3-chlorocarbanilate, $C_{10}H_{12}ClNO_2$, M_r 123.7, *mp* 41.4 °C, is a colorless solid which is moderately soluble in water and readily soluble in most organic solvents [23, p. 233].

Chlorpropham is produced by reaction of *m*-chloroaniline with isopropyl chloroformate [132].

Chlorpropham, a cell-division inhibitor, is a selective herbicide used pre-emergence for the control of annual grasses and some broad-leaved weeds in many crops.
Trade Names. Decco Aerosol 273 (Elf Atochem); Prevenol (AgrEvo), etc.

Cycloate [*1134-23-2*], *S*-ethyl cyclohexyl(ethyl)thiocarbamate, $C_{11}H_{21}NOS$, M_r 215.4, *bp* 145 – 146 °C/10 mmHg, is a colorless liquid which is moderately soluble in water and miscible with most organic solvents [23, p. 285].

Cycloate is produced by reaction of *N*-cyclohexyl-*N*-ethylcarbamoyl chloride with ethylmercaptan [133].

Cycloate is a lipid-metabolism inhibitor which is used pre-planting and soil-incorporated for the control of annual grass weeds and some perennial grasses and broad-leaved weeds in sugar beet, fodder beet, spinach, etc.
Trade Names. Ro-Neet (Zeneca); Sabet (Sanachem), etc.

Desmedipham [*13684-56-5*], ethyl 3-phenyl- carbamoyloxyphenylcarbamate, $C_{16}H_{16}N_2O_4$, M_r 300.3, *mp* 120 °C, forms colorless crystals which are moderately soluble in water and readily soluble in polar organic solvents [23, p. 349].

Desmedipham is produced by reaction of *m*-aminophenol with ethyl chloroformate, followed by treatment with phenyl isocyanate [134].

Desmedipham, a photosynthesis electron-transport inhibitor, is a selective herbicide used post-emergence to control broad-leaved weeds in beet crops, etc.
Trade Names. Betanal AM, Kemifam (AgrEvo), etc.

Dimepiperate [*61432-55-1*], *S*-(1-methyl-1-phenylethyl)piperidine-1-carbothioate, $C_{15}H_{21}NOS$, M_r 263.4, *mp* 38.8 – 39.3 °C, is a waxlike solid which is moderately soluble in water and fairly soluble in acetone, chloroform, cyclohexanone, ethanol, and hexane [23, p. 404].

Dimepiperate is produced by reaction of benzene isopropylmercaptan with piperidine carbamoyl chloride [133].

Dimepiperate, a lipid-metabolism inhibitor, is a systemic herbicide used for the control of *Echinochloa crusgalli* in flooded rice.
Trade Name. Yakamate (Mitsubishi).

EPTC [*759-94-4*], *S*-ethyl dipropylthiocarbamate, $C_9H_{19}NOS$, M_r 189.3, *bp* 127 °C/20 mmHg, is a colorless liquid which is moderately soluble in water and is miscible with common organic solvents [23, p. 466].

$[CH_3(CH_2)_2]_2NC(O)SCH_2CH_3$

EPTC is produced by reaction of di-*n*-propylamine with phosgene, followed by treatment with ethylmercaptan [135].

EPTC, a lipid-metabolism inhibitor, is a selective herbicide used pre-planting with soil-incorporation for the control of annual and perennial grasses and some broad-leaved weeds in many crops.
Trade Names. Eptam, Eradicane (Zeneca); Alirox (Sagrochem), etc.

Esprocarb [*85785-20-2*], *S*-benzyl 1,2-dimethylpropyl(ethyl)thiocarbamate, $C_{15}H_{23}NOS$, M_r 265.4, *bp* 135 °C/35 mmHg, is a liquid which is moderately soluble in water and is fairly soluble in ethanol, chloroform, xylene, acetone, and acetonitrile [23, p. 472].

Esprocarb is produced by reaction of *N*-ethyl-*N*-(methyl)isobutylcarbamoyl chloride with mercaptotoluene [133].

Esprocarb is a lipid-metabolism inhibitor, which is used pre- and post-emergence for the control of annual weeds and *Echinocloa* sp. in paddy rice.
Trade Names. Fujigrass (Du Pont, Zeneca); Sparkstar (Nissan, Zeneca), etc.

Molinate [*2212-67-1*], *S*-ethyl azepane-1-carbothioate, $C_9H_{17}NOS$, M_r 187.3, *bp* 136.5 °C/10 mmHg, is a colorless liquid which is moderately soluble in water and is miscible with most organic solvents [23, p. 847].

Molinate is produced by reaction of chlorothiolformate with hexamethyleneimine [136].

Molinate, a lipid-metabolism inhibitor, is a selective, systemic herbicide used to control germinating broad-leaved weeds and grasses, and is applied either before planting, to water-seeded-, to shallow-soil-seeded-, or to post-flood rice.
Trade Names. Ordram (Zeneca); Sakkimol (Sagrochem), etc.

Orbencarb [*34622-58-7*], *S*-2-chlorobenzyl diethylthiocarbamate, $C_{12}H_{16}ClNOS$, M_r 257.8, *mp* 9.0 °C, *bp* 158 °C/1 mmHg, is a colorless liquid which is moderately soluble in water and readily soluble in most organic solvents [23, p. 898].

Orbencarb is produced by reaction of 2-chloro-mercaptotoluene with *N*-diethylcarbamoyl chloride [133].

Orbencarb is a selective herbicide used pre-emergence to control broad-leaved weeds in barley, wheat, rye, maize, soya beans, cotton, and turf.
Trade Name. Lanray (Kumiai).

Pebulate [*1114-71-2*], *S*-propyl butyl(ethyl)thiocarbamate, $C_{10}H_{21}NOS$, M_r 203.3, *bp* 142 °C/21 mmHg, is a colorless to yellow liquid which is moderately soluble in water and is miscible with most organic solvents [23, p. 930].

Pebulate is produced by reaction of ethylbutylamine with phosgene, followed by treatment with propylmercaptan [137].

Pebulate, an inhibitor of the biosynthesis of very long chain fatty acids, is a selective, systemic herbicide used pre-emergence and soil-incorporated to control annual grasses and some broad-leaved weeds in sugar beet, tomatoes, etc.
Trade Name. Tillam (Zeneca).

Phenmedipham [*13684-63-4*], methyl 3-(3-methylcarbaniloyloxy)carbamate, $C_{16}H_{16}N_2O_4$, M_r 300.3, *mp* 143 – 144 °C, forms colorless crystals which are moderately soluble in water and fairly soluble in polar organic solvents [23, p. 948].

Phenmedipham is produced by reaction of 3-aminotoluene with 3-methylcarbamic benzoyl chloride [134].

Phenmedipham, a photosynthesis electron-transport inhibitor, is a selective, systemic herbicide used post-emergence for the control of most annual broad-leaved weeds in beet crops, strawberries, peas, spinach, etc.
Trade Names. Betanal (AgrEvo); Alegro (Rhône-Poulenc); Beetup (United Phosphorus), etc.

Prosulfocarb [*52888-80-9*], *S*-benzyl dipropylthiocarbamate, $C_{14}H_{21}NOS$, M_r 251.4, *bp* 129 °C/33 Pa, is a colorless liquid which is moderately soluble in water and is miscible with acetone, chloroform, chlorobenzene, ethanol, xylene, and ethyl acetate [23, p. 1039].

Prosulfocarb is produced by reaction of *N*-dipropylcarbamoyl chloride with mercaptotoluene [133].

Prosulfocarb is a lipid-metabolism inhibitor, and is a selective herbicide used pre- and early post-emergence for the control of a wide range of grass and broad-leaved weeds in winter wheat, winter barley, and rye.
Trade Names. Boxer, Defi (Zeneca).

Pyributicarb [*88678-67-5*], *O*-3-*tert*-butylphenyl 6-methoxy-2-pyridyl(methyl)thiocarbamate, $C_{18}H_{22}N_2O_2S$, M_r 330.4, *mp* 85.7 – 86.2 °C, forms colorless crystals which are sparingly soluble in water, fairly soluble in methanol and ethanol, and readily soluble in acetone, xylene, chloroform, and ethyl acetate [23, p. 1060].

Pyributicarb is produced by reaction of 3-*tert*-butylphenol with 6-methoxy-2-*N*-methyl-*N*-thionyl chloride [138].

Pyributicarb is a systemic herbicide used pre- and early post-emergence for the control of annual and perennial grasses and weeds in turf.
Trade Names. Eigen, Isshintasuke (Dainippon).

Thiobencarb [*28249-77-6*], *S*-4-chlorobenzyl diethylthiocarbamate, $C_{12}H_{16}ClNOS$, M_r 257.8, *bp* 126 – 129 °C/0.008 mmHg, is a pale yellow to brownish yellow liquid which is moderately soluble in water and is readily soluble in acetone, ethanol, xylene, methanol, benzene, and acetonitrile [23, p. 1192].

Thiobencarb is produced by reaction of *p*-chloromercaptotoluene with *N*-diethylcarbamoyl chloride [133].

Thiobencarb is a protein-synthesis inhibitor, and is a selective herbicide used pre- and early post-emergence for the control of a number of grasses and weeds in rice.
Trade Names. Saturn (Kumiai); Bigturn (Sanonda); Bolero (Valent), etc.

Triallate [*2303-17-5*], *S*-2,3,3-trichloroallyl diisopropyl(thiocarbamate), $C_{10}H_{16}Cl_3NOS$, M_r 304.7, *mp* 29 – 30 °C, is a yellow to brown solid which is moderately soluble in water and readily soluble in common organic solvents [23, p. 1220].

$[(CH_3)_2CH]_2NCOSCH_2CCl{=}CCl_2$

Triallate is produced by reaction of isopropylamine with phosgene, followed by coupling with 1,1-dichloro-2-chloro-3-mercapto-1-propylene [139].

Triallate inhibits fatty acid and lipid biosynthesis, and is a selective herbicide used pre- or post-planting and soil-incorporated for the control of wild oats and some annual grasses in wheat, barley, rye, field beans, etc.
Trade Names. Abrade BW (Monsanto, Du Pont); Frau-Go (Monsanto), etc.

Vernolate [*1929-77-7*], *S*-propyl dipropylthiocarbamate, $C_{10}H_{12}NOS$, M_r 203.3, *bp* 150 °C/30 mmHg, is a colorless liquid which is moderately soluble in water and miscible with common organic solvents [23, p. 1264].

$(CH_3CH_2CH_2)_2NCOSCH_2CH_2CH_3$

Vernolate is produced by reaction of *N*-dipropylcarbamoyl chloride with propylmercaptan [133].

Vernolate inhibits lipid metabolism, and is a selective herbicide used soil-incorporated, either pre-planting or post-emergence, for the control of germinating broad-leaved weeds and grasses in peanuts, maize, soya beans, tobacco, sweet potatoes, etc.
Trade Name. Vernam (Zeneca).

7.8.14. Organophosphates

Anilofos [*64249-01-0*], *S*-(4-chloro-*N*-isopropylcarbaniloxymethyl)-*O*,*O*-dimethyl phosphorodithioate, $C_{13}H_{19}ClNO_3PS_2$, M_r 367.8, *mp* 50.5 – 52.5 °C, is a crystalline solid which is moderately soluble in water and is readily soluble in acetone, chloroform, toluene, benzene, ethanol, dichloromethane, and ethyl acetate [23, p. 47].

Anilofos is produced by reaction of *O*,*O*-dimethylphosphorodithioate with *p*-chlorobenzene-*N*-isopropylcarbamoyl chloride [140].

Anilofos is a selective herbicide used to control annual grasses and sedges in transplanted rice.

Trade Names. Arizon, Rico (AgrEvo); Anilogard (Gharda).

Bensulide [*741-58-2*], *S*-2-benzenesulfonamidoethyl-*O*,*O*-diisopropyl phosphorodithioate, $C_{14}H_{24}NO_4PS_2$, M_r 397.5, 34.4 °C, is a colorless solid which is moderately soluble in water and is readily soluble in acetone, ethanol, and xylene [23, p. 106].

Bensulide is produced by reaction of *O*,*O*-diisopropylphosphorodithioate with *N*-chloroethylbenzene sulfonamide [141].

Bensulide is a selective herbicide used pre-emergence on cotton, on some vegetables, and also on established turf.

Trade Names. Betasan, Prefar (Gowan); Bensumac, Pre-San (PBI/Gordon); Lawnpur (Tomen).

Bilanafos [*35597-43-4*], 4-[hydroxy(methyl)- phosphinoyl]-L-homoalanyl-L-alanine, $C_{11}H_{22}N_2O_6P$, M_r 323.3, is readily soluble in water and practically insoluble in organic solvents [23, p. 120].

Bilanafos is produced by reaction of 2-nitro-5-phenol with phosphorus trichloride, followed by treatment with sulfur, and then with ethanol and 2-butylamine [142].

Bilanafos is a glutamine-synthase inhibitor, and is used post-emergence for the control of annual weeds in vines, apples, brassicas, rubber, etc. It is also used to control annual and perennial weeds in uncultivated land.

Trade Names. Meiji, Herbiace (Meiji Seika).

Butamifos [*36335-67-8*], *O*-ethyl-*O*′-6-nitro-*m*-tolyl *sec*-butylphosphoramidothioate, $C_{13}H_{21}N_2O_4PS$, M_r 332.4, is a yellow-brown liquid which is moderately soluble in water and is readily soluble in acetone, methanol, and xylene [23, p. 161].

Butamifos is produced by reaction of 2-nitro-5-methylphenol with *O*-ethyl-*N*-*sec*–butylphosphoramidothionyl chloride [143].

Butamifos is a selective, nonsystemic herbicide used pre-emergence to control annual weeds in beans, rice, vegetables, etc.

Trade Name. Cremart (Sumitomo).

Glufosinate-ammonium [*77182-82-2*], ammonium 4-[hydroxy(methyl)phosphinoyl]-DL-homoalaninate, $C_5H_{15}N_2O_4P$, M_r 198.2, *mp* 125 °C, forms a colorless crystalline solid which is readily soluble in water and moderately soluble in acetone, ethanol, ethyl acetate, toluene, and hexane [23, p. 643].

Glufosinate-ammonium is produced by reaction of *O*,*O*-diethylmethylphosphonate with 2-amino-4-bromobutanoic acid [144].

Glufosinate-ammonium, a glutamine-synthase inhibitor, is a nonselective contact herbicide used for the control of a wide range of annual and perennial broad-leaved weeds and grasses in fruit orchards, vineyards, rubber and oil palm plantations, ornamental trees and brushes, noncropland, and pre-emergence in vegetables.

Trade Names. Basta, Liberty (AgrEvo).

Glyphosate [*1071-83-6*], *N*-(phophonomethyl)glycine, $C_3H_8NO_5P$, M_r 169.1, *mp* 189.5 °C, forms colorless crystals which are fairly soluble in water and are insoluble in common organic solvents [23, p. 646].

Glyphosate is produced by heating a mixture of phosphorous acid and α-amino acetic acid, and then adding formaldehyde [145].

Glyphosate inhibits enolpyruvylshikimi-3-phosphate synthase and is a nonselective herbicide used pre-harvest, post-planting/pre-emergence to control annual and perennial grasses and broad-leaved weeds in stubble, cereals, peas, beans, oilseed rape, flax, mustard, etc.

Trade Names. Rodeo, Roundup, Sting (Monsanto); Touchdown (Zeneca); Barbaran (Barclay); Sanos (Sanonda), etc.

Piperophos [*24151-93-7*], *S*-2-methylpiperidinocarbonylmethyl *O*,*O*-dipropyl phosphorodithioate, $C_{14}H_{28}NO_3PS_2$, M_r 353.5, *bp* > 250 °C, is a pale yellow slightly viscous colorless liquid which is moderately soluble in water and is miscible with benzene, hexane, acetone, dichloromethane, and ethanol [23, p. 983].

Piperophos is produced by reaction of *O*,*O*-diisopropylphosphorodithioate with 1-methylpiperidinylcarboxy chloride [146].

Piperophos is a selective, systemic herbicide used to control annual grasses and sedges in directly seeded or transplanted rice.

Trade Name. Rilof (Novartis).

7.8.15. Cyclohexanedione Oximes

Alloxydim-sodium [*66003-55-2*], methyl (*E*)-(*R*,*S*)-3-[1-(allyloxyimino)butyl]-4-hydroxy-6,6-dimethyl-2-oxocyclohex-3-enecarboxylate, $C_{17}H_{24}NNaO_5$, M_r 345.4, *mp* 185.5 °C, forms colorless crystals which are readily soluble in water, dimethylformamide, and methanol and are fairly soluble in ethanol, methyl ethyl ketone, acetone, cyclohexanone, ethyl acetate, and xylene [23, p. 30].

Alloxydim-sodium is produced by reaction of mesityloxide with dimethyl malonate; the resultant product is then treated with *n*-butyryl chloride, followed by reaction with hydroxyallylamine; finally the ester is hydrolyzed to the acid [147].

Alloxydim-sodium inhibits mitosis and fatty acid synthesis; it is a selective, systemic herbicide used post-emergence for the control of grass weeds and volunteer cereals in sugar beet, vegetables, and broad-leaved crops.

Trade Names. Clout (Rhône-Poulenc); Kusagard (Nippon Sosa); Frevin (AgrEvo), etc.

Clethodim [*99129-21-2*], (±)-2-[(*E*)-1-[(*E*)-3-chloroallyloxyimino]propyl]-5-[2-(ethylthio)propyl]-3-hydroxycyclohex-2-enone, $C_{17}H_{26}ClNO_3S$, M_r 359.9, is an amber liquid which insoluble in most organic solvents [23, p. 250].

Clethodim is produced by reaction of ethylmercaptan with crotonal, followed, successively, by treatment with acetone, dimethyl malonate, hydrolysis reagents, propionic acid chloride, and α-chlorohydroxyallylamine [148].

Clethodim, a fatty-acid-synthesis inhibitor, is a systemic herbicide used post-emergence for the control of annual and perennial grasses in a wide range of broad-leaved crops, vegetables, trees, and vines.

Trade Name. Select (Tomen, Valent).

Cycloxydim [*101205-02-1*], (±)-2-[1-(ethoxyimino)butyl]-3-hydroxy-5-thian-3-ylcyclohex-2-enone, $C_{17}H_{27}NO_3S$, M_r 325.5, *mp* 41 °C, consists of colorless crystals which are moderately soluble in water, are readily soluble in acetone, ethanol, dichloromethane, and ethyl acetate, and are fairly soluble in *n*-hexane [23, p. 290].

Cycloxydim is produced by reaction of 2-butyryl-5-[2-(1,3-dioxan-2-yl)ethyl]-1,3-cyclohexanedione with hydroxyethylamine [149].

Cycloxydim, which inhibits fatty acid synthesis, is a selective herbicide used post-emergence to control annual and perennial grasses in broad-leaved crops.

Trade Names. Focus, Lasre, Stratos (BASF).

Sethoxydim [*74051-80-2*], (±)-(*E*,*Z*)-2-(1-ethoxyiminobutyl)-5-[2-(ethylthio)propyl]-3-hydroxycyclohex-2-enone, $C_{17}H_{29}NO_3S$, M_r 327.5, *bp* $> 90\,°C/3 \times 10^{-5}$ mmHg, is an oily liquid which is fairly soluble in water and readily soluble in most organic compounds [23, p. 1101].

Sethoxydim is produced by reaction of ethylmercaptan with crotonal, followed by reaction with acetone, dimethylmalonate, hydrolysis reagents, butyryl chloride, and hydroxyethylamine [148].

Sethoxydim, which inhibits fatty acid synthesis, is a selective herbicide used to control annual and perennial grasses in broad-leaved crops.

Trade Names. Naba (Nippon Soda); Fervinal (AgrEvo); Poaset (BASF).

Tepraloxydim (BAS 620H) [*149979-41-9*], (*E*,*Z*)-(*R*,*S*)-2-{1-[(2*E*)-3-chloroallyloxyimino]propyl}-3-hydroxy-5-perhydropyran-4-ylcyclohex-2-en-1-one, $C_{17}H_{24}ClNO_4$, M_r 341.8 [23, p. 80].

Tepraloxydim is prepared by condensation of 5-perhydropyranyl-3-hydroxy-2-carbonylpropylcyclohex-2-ene-1-one with chloroallyloxyamine [150].

Tepraloxydim is under development for use in soya beans and cotton (BASF).

Tralkoxydim [*87820-88-0*], 2-[1-(ethoxyimino)propyl]-3-hydroxy-5-mesitylcyclohex-2-enone, $C_{20}H_{27}NO_3$, M_r 329.4, *mp* 106 °C, consists of colorless crystals which are fairly soluble in water, hexane, methanol, and acetone and are readily soluble in ethyl acetate, toluene, and dichloromethane [23, p. 1211].

Tralkoxydim is produced by condensation of 2,4,6-trimethylbenzaldehyde with acetone, followed by condensation with diethyl malonate, acylation with propionic acid anhydride, and treatment with thioxyamine [151].

Tralkoxydim, an inhibitor of cell division and fatty-acid synthesisr, is a selective herbicide used for the control of *Avena* sp. and other grass weeds in wheat and barley.

Trade Names. Achieve, Grasp (Zeneca).

7.8.16. Benzonitriles

Dichlobenil [*1194-65-6*], 2,6-dichlorobenzonitrile, $C_7H_3Cl_2N$, M_r 172.0, *mp* 145 – 146 °C,

forms colorless crystals which are moderately soluble in water and are fairly soluble in acetone, dioxane, benzene, dichloromethane, xylene, and ethanol [23, p. 359].

Dichlobenil is produced by conversion of 2,6-dichlorotoluene into 2,6-dichlorobenzal chloride, which is converted into 2,6-dichlorobenzaldehyde, 2,6-dichlorobenzaldoxime, and 2,6-dichlorobenzonitrile [152].
